THE TREATMENT OF GASTRO-INTESTINAL CATARRH IN INFANTS, WITH ESPECIAL REFERENCE TO IRRIGATION OF THE INTESTINES.

A Clinical Lecture delivered at the Woman's Medical College of Philadelphia.

BY EDWARD P. DAVIS, M.D.,
OBSTETRICIAN TO THE PHILADELPHIA HOSPITAL, ETC

FROM the many terms employed to designate a disease characterized in infants by inflammation of the digestive tract, with diarrhœa, fever, and exhaustion often resulting fatally, the name gastro-intestinal catarrh has been chosen as best describing the pathology of the affection and embracing all grades of its severity. Cholera infantum may fairly designate cases not frequent in which the severity of the affection and rapidly fatal result closely simulate Asiatic cholera.

We shall obtain a better understanding of the pathology of this disease if we first consider some points regarding normal digestion in infants. It has been shown by Koch that lactic acid is wanting in the gastro-intestinal tract of patients dying with Asiatic cholera, and it might reasonably be inferred that lactic fermentation is part of the processes of normal digestion. Recent studies by Baginsky and Leo have confirmed this inference so far as the digestion of infants is concerned. The stomach of the newborn child does not contain pepsin as an active ferment, but digests by the action of lab ferment and zymogen, and when cow's milk is taken hydrochloric acid is secreted in excess. The lactic fermentation or hydro-lactic acid digestion is present normally, and it is not this process, but a further acid fermentation resulting in the change of the neutral lactates to butyric acid, with the formation of acetic acid and acetone, which is pathological; the digestion of starch, casein, and albumin is checked simultaneously with the formation of the acetic compounds.

The bacteria, whose presence accompanies the lactic fermentation, are adjuvants in normal digestion, and their activity is not to be checked; it is the excessive formation of bacteria arising through failure of the inhibitory function of the lactic bacteria which is to be combated. Examination of the adult stomach reveals the presence of bacteria in abundance, whose function in normal digestion is to aid in splitting up ingested foods. There are, then, bacteria and bacteria, some benign and adjuvant, others malignant and destructive, according to the part they bear in aiding or hindering digestion.

Regarding the causation of gastro-intestinal catarrh, its active cause is most often irritating food; its predisposing causes are those which favor vaso-motor paralysis and blood-stasis in the digestive organs, as exposure to cold and the depressing effect of heat on the vaso-motor centres. And the severity of a given attack of this disease will depend upon the presence and potency of the active cause in addition to the predisposing causes. An infant exposed to a sudden cool change in summer may suffer from congestion of the digestive organs, with transudation of serum and hypersecretion of the mucous membrane of the digestive tract; if the child's food be lessened and be free from fermentation and irritating matter, nature soon cures the case with a few loose stools which relieve congestion and cause the gastro-intestinal catarrh to cease. If, however, upon this condition of blood-stasis and hypersecretion the acetic bacteria and irritating products of their activity be grafted, a general gastro-intestinal catarrh results attended by the rapid growth of bacteria and structural lesions of a grave nature.

Distinguishing, therefore, between the predisposing and active causes of the disease in question, we find that the most important factor in producing active causes is heat. When the average temperature for twenty-four hours is so high as to favor the decomposition of the albuminoid envelope of the fat drop which forms the milk globule, milk ceases to be an unirritating food and becomes an active irritant and conveyer of pathogenic bacteria. Milk is ordinarily taken from the cow early in the morning, and delivered to the consumer before 9 or 10 A.M. When the night temperature rises disease caused by irritating milk increases; in early autumn it is less frequent so soon as the nights become cool although the days are warm. Not only is milk affected by heat, but the water of ponds, lakes, and rivers contains an increased quantity of fermented material and bacteria so soon as the night temperature permits the continuous decomposition of vegetable and animal albuminoids contained in leaves and twigs, and in the bodies of birds and fish. Milk and water under certain average temperatures are very liable to become active causes of gastro-intestinal catarrh.

The pathology of these cases varies from that of simple blood-stasis and transient hypersecretion to the development of well-marked ulceration of the large intestine with profound anæmia of vital organs and passive congestion in the cerebral sinuses. In cases which seem to survive the disease only to perish later in collapse, no gross lesion is found sufficient to explain the fatal issue, and marasmus expresses our ignorance of the pathology of these cases. It is not improbable that atrophy of the gastric tubules resembling that found in adults in pernicious anæmia is present in such cases. Examination of the stools in cases attended by intestinal lesions reveals undigested food, pus, and bacteria in abundance; when chemically examined fat is present in increased quantities, showing failure of pancreatic digestion.

The symptoms of a compensatory catarrh following simple congestion are moderate fever, restlessness, thirst, and frequent liquid-yellow stools often containing mucus. In severe cases fever becomes high, restlessness is well

marked; thirst excessive; profound anæmia soon discloses itself; stupor, coma, or convulsions, a clammy skin, and relaxed sphincters precede death. Stools are very frequent, watery, serous or very dark in color; green, or chocolate, or coffee-ground in appearance, and sometimes extremely fetid. In considering the color of a stool, its color immediately on passage should be noted, as the bile compounds assume darker hues on oxidation in the diaper, which may mislead. In rapidly fatal cases, styled cholera infantum, the picture of Asiatic cholera in the adult is reproduced in miniature. Extreme prostration, "rice water" stools in rapid succession, cadaveric appearance, clammy skin, and death in coma decide the fate of the child in a few hours; there is little time to study the stages of disease, and therapeutic expedients are tried in vain.

In discussing the treatment of gastro-intestinal catarrh in infants, prophylaxis is of major importance. The fact that congestion of the abdominal viscera, with simple hypersecretion of the digestive mucous membrane, furnishes the most favorable condition for the development of serious disease, should not be overlooked. The child's skin should be kept in a condition of healthy activity, fitting it to withstand changes of temperature, by regular baths in tepid water; thin flannel should be worn next the skin, covering the child's body and limbs to the wrists and ankles. The expedient of European residents in India may be adopted, and an abdominal band of flannel worn beneath the shirt. It will be found much more healthful and comfortable to discard outer wraps in hot weather, and clothe the child entirely in flannel, using as few garments as possible. So clad, an infant may pass the greater portion of its day in the open air with little danger of taking cold. The hygiene of the child's dwelling is also of great importance. Air space, freedom from decaying vegetable and animal matter, and immunity from conditions preventing sleep, are essential.

But especial attention should be paid to the infant's ingesta. Infective material should be excluded or neutralized in food and drink. Water should be filtered and boiled before given as a beverage or with milk. Milk should be sterilized, by apparatus designed for that purpose, or by boiling. All albuminoid food liable to decomposition should be thoroughly heated; the many "teas" mixed for infants by meddlesome women are abominations. The nursing-bottle should be frequently scalded, washed in water containing soda, and the rubber nipples should be kept in a saturated solution of borax. When apparatus for sterilizing milk is not available, it may be boiled in a glass fruit jar, which is placed in a pan of water upon the fire; the impervious lid may then be applied, and the milk set away to cool until needed.

It is far better, however, to sterilize milk in the bottle from which the infant feeds. Numerous sterilizers are in the market, the essential principle of all being the same. They consist of a tin or wire rack holding bottles containing milk, which rests upon a shoulder or ledge several inches above the bottom of a closed tin box. The bottles having first been sterilized by boiling water or dry heat, are partially filled with milk, or milk and boiled water. They are then corked by a rubber cork perforated for a glass stopper. The glass stopper is withdrawn, the bottles placed in the closed tin box, which contains three or four inches of water, and the whole is heated until the water boils for half an hour. The process should be watched as the water heats to boiling, and when that point is reached the glass stoppers are replaced in the rubber corks, and the bottles thus sealed. The bottles are set aside to cool.

When needed for feeding, a teaspoonful of a good extract of malt is added to 4 to 6 ℥ of milk and the bottle is heated in water to a proper temperature, a freshly cleaned rubber nipple is substituted for the rubber cork, and the infant receives its meal from the vessel in which it was sterilized without exposure of the milk to the air. This process may be simplified by substituting for the rubber cork a plug of cotton sterilized by heat. Cotton plugs are in common use as air filters to prevent the access of bacteria in culture experiments, and their use seems indicated to close vessels in sterilizing milk. Extract of malt is preferred to sugar because less likely to ferment.

In hospitals and homes, where a number of children are collected, all diapers should be disinfected by immersion in a solution of bichloride of mercury, 1 to 5000 or 10,000. With every precaution stools are retained in the diaper for varying periods, and it is well to prevent the sporulation of bacteria during this time. For the child's person, strict cleanliness is necessary; finely powdered boracic acid may be used to advantage as a toilet powder when a tendency to excoriation exists.

The active treatment of a simple congestion of the digestive mucous membrane, with compensatory catarrh, should be the withdrawal of food for several hours, a warm bath, and a free supply of boiled water in small quantities as a beverage; should prostration threaten, whiskey and water, or aromatic spirits of ammonia and water, may be given. It is especially true of infants that loss of fluid is felt severely, and a few liquid stools in a young child cause distinct depression. If nature does not move the bowels promptly, castor oil may be given.

Should vomiting of curded milk occur, with pronounced gastric irritation, the stomach may be washed out to advantage. A small soft catheter (No. 8), a short piece of glass tubing, and a longer rubber tube and small funnel are sufficient, the glass tubing connecting the catheter and rubber tubing and serving as an index of the passage of fluid. Boiled water containing a little sodium bicarbonate or sodium salicylate (gr. 1 to ℥ 1) may be employed. The tongue is gently but firmly depressed with the index finger of the left hand, and with the right the oiled catheter is passed backward and downward; meeting resistance a pause is made, the catheter rotated gently, and usually enters the œsophagus without difficulty. The fluid should be poured into the funnel very gently, and allowed to return by siphonage, until it returns clear.

Although gastric ulcer and rupture of the stomach are uncommon in infants, yet in a recent series of experiments made by my friend Dr. Bennett, physician in charge of the Sea Side Home, Atlantic City, to determine the probability of rupturing the gastro-intestinal tract by irrigation, he found on the cadaver that the few cases of rupture occurring on post-mortem irrigation were in the stomach, where beginning ulceration existed. Gastric irrigation should be made with great gentleness and patience, and should be undertaken only when gastric irritation is pronounced. The omission of one or two meals may be followed, if symptoms disappear, by a re-

sumption of sterilized milk and water in diminished quantities; skimmed mutton broth or white of egg water may be employed if milk is not tolerated at once.

Should the case go on to well-marked intestinal catarrh with enteritis a more decided policy must be adopted. An effort should at once be made to remove irritating ingesta from the intestines, to prevent the growth of bacteria, and to feed and support the patient in every possible way. An intestinal antiseptic is indicated, and from experience calomel seems best fitted for an early stage of the disease. In $\frac{1}{10}$ or $\frac{1}{20}$ grain doses, with soda or milk sugar, it may be given every hour or half hour until the stools show a free secretion of bile. For the first six or eight hours food should be replaced by teaspoonfuls of whiskey and boiled water or Jacobi's mixture of white of egg and whiskey and water, care being taken that fluid in *small* quantities is taken very freely. Temperature may be reduced by the warm or hot bath, a cold cloth upon the head. A spice plaster upon the abdomen may often be used to advantage. If pain and restlessness, with fever, are not controlled by the bath antipyrin in one-half grain doses may replace opium to advantage.

If the antiseptic action of Nature's intestinal antiseptic the bile and calomel are not sufficient to check the growth and invasion of bacteria, intestinal irrigation should be promptly undertaken, *before* prostration supervenes. A soft catheter (No. 11), a connecting glass tube, and fountain syringe are needed. The fluid may be boiled water made alkaline by sodium bicarbonate; thymol 1 to 1000, or sodium salicylate gr. 20 to ℥ 20 of water (the last is highly prized by Dr. Bennett). Through the courtesy of Dr. Waterman, of the clinical staff of the College, I have a case in which intestinal irrigation is indicated. The child is laid across the lap of the nurse who receives it on its abdomen upon a rubber sheet gathered into a pail below. Placing the back of the left hand against the child's nates the oiled catheter is introduced by the right hand and pushed gently into the bowel. As it advances it is held by the thumb and finger of the left hand while the right rotates it; if a decided obstruction presents, it is slightly withdrawn and then advanced.

The catheter may be introduced six or eight inches without difficulty; the fountain syringe should be held from two to three feet above the patient and fluid allowed to flow freely. The temperature of this fluid should be from 90° to 110° F.; if the child is in collapse, a hot irrigation is a decided stimulant. The quantity of fluid may vary from ℥ 20 to a quart and a half; in collapse, after the fluid returns clear several ounces of hot water or hot whiskey and water may be introduced into the bowel for absorption to decided advantage. As you see in the patient before you, while the introduction of the catheter may be resented the passage of fluid is a positive comfort, and it is not an unusual occurrence for infants to fall asleep on the nurse's lap while receiving intestinal irrigation and sleep for an hour or two, the temperature falling considerable. The pressure of the child's body as it lies prone upon the nurse's lap secures a free return flow of fluid, and there is little danger of doing violence to the intestines, for the abdominal wall is undergoing distention and not the intestine, as shown in Dr. Bennett's experiments. Intestinal irrigation may be employed twice daily without injury to the patient, and even more often in urgent cases.

Should the case become chronic, naphthaline or salol may be given to advantage; salol, with mercury and chalk, has served me well. But the maintenance of the patient's strength, the removal of irritating ingesta, the preservation of the conditions most favorable for the circulation of blood, avoidance of passive congestion, and finally the gradual reëstablishment of digestion, these form a problem requiring the most painstaking attention to each case. The fortunes of these little patients are decided often in a few hours, and having tided them over an acute attack a restoration to health may now follow speedily.

If not, the problem of nutrition is first to be solved. Mutton, veal, and chicken broth; flour ball; barley water; junket; a good extract of malt; English breakfast tea and rum (a favorite stimulant for children with Continental physicians), warm milk from the cow have all benefited individual cases. Change of air may turn the tide when nothing else will. Arsenic, in small, but steadily increasing doses, with olive oil, almond flour, or butter may be tried. Oil inunctions are also useful. The peptonizing and pancreatizing powders sold by druggists are often useful in pre-digesting milk.

But it is my experience and conviction that your success in treating gastro-intestinal catarrh in infants will depend more upon your clear understanding of the causes of the disease and the way to avoid them; your knowledge of its pathology, and your close study of each case and intelligent use of the simplest and most direct methods of antiseptic and supporting treatment than in the drugs you employ or the particular brand of artificial food used. You may not increase the profits of the manufacturers and dealers of patented foods, but it will be to the profit of your patients.

VULVO-VAGINITIS IN CHILDREN.

By ANDREW F. CURRIER, M.D.,
of New York.

If we recall for a moment a few points concerning the anatomy of the external female genitals in childhood, we will observe that they are unprotected by hair, the nymphæ are relatively more prominent and protuberant than they are after puberty, both the large and the minute glands are less active functionally than in mature life, and the entrance to the vagina is less conspicuous and is more or less obscured by the hymen. As Leishman remarks, the conformation suggests the greater importance of the urinary, compared with the genital organs, during the developmental period of the structures of the body. But it also means that the external genitals, with increased susceptibility to infection during childhood, are more exposed, should opportunity for infection arise. In other words, an opportunity which in a child would result in vulvo-vaginitis might not so result in an adult.

The infectious element may be communicated

either to the vulva or the vagina and the resulting inflammation extend in either direction, but for reasons which are obvious the vulva is more likely to be first involved. Either vulvitis or vaginitis may exist alone, but more frequently the infectious disease which begins with the vulva does not end there. In adults this disease not infrequently extends to the uterus, the Fallopian tubes, the ovaries, and the peritoneum, and may end fatally. I can find but one recorded case in which such extension occurred in children, but it seems to me extremely probable that many of the deformed and undeveloped uteri with which are associated so much dysmenorrhœa and anguish, sterility and domestic unhappiness are the legitimate consequence of vulvo-vaginitis in early life.

If this is so, an increased responsibility is laid upon mothers and family physicians that the disease be not ignored from feelings of false modesty or any other consideration. Modesty is, indeed, one of the most beautiful attributes which human beings possess, but it is a false and utterly unworthy sentiment when it interferes with the present or prospective well-being of the one for whom it is exercised. Confidence in the ability and integrity of a physician is one of the first requisites in the relations which subsist between physician and patients; in fact, how can one do his full duty if this confidence is withheld? Not until this is more fully realized and practised can we hope for that powerful interference in the beginnings of disease which will enable us to anticipate more serious resulting disorders, and not until then can our children be properly equipped physically for the responsibilities of maternity with all that is therewith implied for the family and the State.

Vulvo-vaginitis is not in all cases the result of infection; it may be associated with and be the expression of various constitutional vices, it may be caused by traumatism of various kinds and degrees, or it may be due to the influences of parasites other than the parasitic microörganisms of infectious disease. When we consider the susceptibility of infants and children to infection, and the fact that so many of the diseases which are common among them are now believed to be the result of an infectious agent, we are prepared to admit that by far the larger number of cases of vulvo-vaginitis are of infectious origin. The disease may be congenital—an infant may be as readily infected with this disease by its mother during parturition, as with ophthalmo-blenorrhœa, and there are few, if any, who will now question the possibility of the latter. That it is less common than ophthalmo-blenorrhœa is probably due to the fact that breech presentations are far less common than vertex presentations, though I am prepared to believe that vulvo-vaginitis may be contracted even in cases in which the head presents. The congenital form of the disease may also be associated with such exanthemata as measles and scarlet fever which not infrequently develop during fœtal life.

The infectious character of the disease is well demonstrated in various epidemics which have been observed in recent years. Von Dusch reports such an epidemic which he observed in the Heidelberg hospital for children in 1886, and again in 1888, the disease being contracted in nearly half the cases after the children had entered the hospital (*Deutsche med. Wochen.*, 1888, p. 831). Other similar epidemics have been reported by Suchard (*Rev. mens. des Mal. de l' Enf.*, 1888, p. 265); Sarazin (*Rev. mens. des Mal. de l' Enf.*, May, 1884); Tischendorf (quoted by De Amicis, *Lyon Méd.*, October 26, 1884); Cséri (*Pester Med. Chirur. Presse*, 1885, No. 1); Fränkel (*Virchow's Archiv*, xcix. p. 251), Bouchut, and Atkinson (quoted by von Dusch, *loc. cit.*).

The traumatic form of the disease may be due to self-inflicted injury, as in masturbation, the introduction of stones, sticks, or shells into the vagina, to falls and blows, and, in some cases, to more or less successful attempts at rape. There is no crime which excites public sympathy and indignation more than rape, and there are few which have a severer penalty; it is, therefore, imperative that the physician who is called upon for an opinion should approach such cases in the calmest judicial spirit, that he may not be the instrument of injustice to accuser or accused.

The etiology of the parasitic form, at least as it is ordinarily given in the text-books on pediatrics, furnishes the opportunity for scepticism. As high an authority as Baginsky speaks of the migration of *oxymi* from the rectum into the vagina, where they deposit their *ova*, which, when developed, give rise to vulvo-vaginitis. Other authorities mention similar migrations on the part of other varieties of intestinal worms with like results. This may be possible, but I agree with Reeves Jackson in expressing scepticism concerning it. It would seem as if the irritation from worms in the rectum, with the resulting mucous discharges dripping upon the anus and external genitals, the rubbing and irritation of dirty fingers would suffice for the production of the disease.

Baginsky's classification of this disease, which is practically that of Vogel's, is a good and comprehensive one, and includes (1) the catarrhal and gonorrhœal variety, (2) the phlegmonous, (3) the diphtheritic, (4) the gangrenous. I have preferred to modify this into (1) the simple catarrhal, (2) the gonorrhœal, (3) the phlegmonous, (4) the diphtheritic. The catarrhal may be entirely distinct from the gonorrhœal, and the gangrenous is only a stage of the phlegmonous, with perhaps some exceptions.

Simple catarrhal vulvo-vaginitis is the most common variety of the disease. No one who practises obstetrics or pediatrics to any extent fails to see it. A. Jacobi speaks of seeing it in hundreds of cases (*Arch. of Ped.*, 1886, p. 336). It may occur in newborn infants or at any period of childhood. It may be due to various causes, and is far more common among the poor and in hospitals than among those who are well-to-do and are particular about the habits and physical condition of their children. The modern gospel of cleanliness is teaching us the fallacy of the old theory that nature cannot be improved upon, if we consider those nearest nature who herd together like the animals and are equally oblivious with them as to their personal appearance and their home surroundings. It is always the poor, the ignorant, and the dirty who suffer most from "the pestilence that walketh in darkness and the destruction that wasteth at noonday." And so we would look for vulvo-vaginitis and find it in the crowded tenement-house—not so often among those who are well-informed and prosperous. Reference has already been made to its presence in hospitals, and I wish strictly to exclude, in this connection, the gonorrhœal variety, of which several hospital epidemics have been reported. If gonococci are found with the discharges, the disease must be gonorrhœal, though the original source of infection may not be traceable, or else the microörganisms are morphologically identical with gonococci, but of different characteristics. The latter is Fränkel's theory in answer to the objection that in a large number of cases of what was apparently simple catarrhal vulvo-vaginitis gonococci have been found (*Virchow's Arch*, xcix., 1885, p. 251). If it is decided that morphological characteristics are of no value, or of little value, in threading the mazes of bacteriology, it must intensify the difficulties of a study that is already extremely intricate.

The most evident symptom in this variety of the disease is a white or colorless discharge, which is secreted in part by the muciparous glands of the vulva and vagina, and is in part a transudation from the bloodvessels. Intense irritation follows the drying of this discharge upon the skin surrounding the external genitals. The scratching and rubbing of these parts by dirty and germ-laden fingers may cause the development of phlegmonous vulvo-vaginitis. Swelling, or urethral irritation, or glandular disturbance in the inguinal region are not accompaniments of the simple catarrhal variety of the disease.

The cause may be any irritant injury, such as was alluded to in a previous paragraph, a constitutional disease, such as syphilis, rhachitis, or scrofula, want of cleanliness, with accumulation of secretions, etc. It has been observed repeatedly in conjunction with measles and scarlet fever. It is probably a portion of the eruptive process of these diseases, and kindred to the condition which affects the mucous membrane of the eyes, nose, and mouth. Von Dusch (*loc. cit.*) thinks that scarlet fever predisposes to vulvo-vaginitis, and a similar opinion has been expressed by others.

The duration of the disease depends largely upon the conditions with which it is associated. If it accompanies a constitutional disease like rachitis or scrofula it may continue indefinitely or until the general condition is decidedly ameliorated. If it accompanies an acute disease it may not last more than a week or two after treatment has been begun, and treatment is, as a rule, inadmissible until the acute disease has subsided. There are certain cases, especially in dispensary practice, in which the cause cannot be satisfactorily traced, which continue a long time chiefly because they are brought to the physician only at long intervals, and in the meantime his directions are most inefficiently carried out. Such cases furnish no criterion as to the susceptibility of the disease to rapid and complete cure.

Gonorrhœal vulvo-vaginitis is preëminently an infectious disease, and its cause has been so frequently traced to the cause which produces gonorrhœa in the adult—namely, the gonococcus of Neisser—that it is safe to say that this point in its pathology is settled. Even if the microbes are not found, and it is not always an easy matter to find them, the presence of the clinical phenomena of the disease, and especially a history of contact, direct or indirect, with one who has been infected, is sufficient for a diagnosis. Thus we find in the records of hospital cases reported by Fränkel, de Amicis, von Dusch, and Suchard that the disease was transmitted from a few or even a single case which was brought into the hospital for treatment, and that in a short time large numbers of children were suffering with the disease. Upon investigation no adults with this disease were discoverable in the surrouundings of these children. It was found, however, in several of the reports that the children in each hospital were bathed in the same tub, upon the same day; that there was a common stock of soap and towels; and that the attendants were not of superior intelligence, nor particularly discriminating in separating those who were infected when brought to the hospital from the uninfected. With our present knowledge of the insidiousness of such diseases no further investigation in such cases would seem to be necessary. Dirty water-closets, beds and bedding, and other articles of hospital or bedroom furniture are other means by which this disease may be transmitted with great facility. Walker reports (*Arch. of Ped.*, 1886, p. 269) twenty-one cases in which there was a history of contact with parents who had

the disease or with other infected persons who had committed assault and rape.

Allusion has already been made to congenital cases, especially in breech presentations, in which infection was accomplished during parturition. As in simple catarrhal vulvo-vaginitis, the secretion upon the external genitals is usually the chief symptom, but in the gonorrhœal variety it is purulent, the same as in adults, except in very mild cases, and in its later stages. Fränkel, having found only small quantities of epithelium in the secretions which he examined, concluded that the disease does not give rise to the same pains and erosions as in the adult, but this cannot be considered an universal rule, for others, including myself, have found it accompanied with great pain; and as to the erosions, it is often impracticable and almost impossible to examine with sufficient thoroughness to decide as to that, unless the child is anæsthetized at each examination.

I have found the clinical phenomena in acute cases closely resembling those which I have described in former papers concerning this disease in adults. (See *New York Med. Journ.*, Jan. 10 and 24, 1885, and Oct. 17 and 24, 1885.) The external genitals are swollen, the mucous membrane has an appearance resembling wet hemlock sole leather, there is exquisite sensitiveness to the touch, and there is sometimes severe pain in urination. Suchard reports cases in which the inguinal glands were enlarged and painful. Hatfield (*Arch. of Ped.*, 1886, p. 64) has seen similar cases, and reports one in which peritonitis resulted. The disease may therefore follow the same course as in the adult.

In common with other observers, I have found that it may be very intractable and rebellious to treatment, even continuing for months. The medico-legal bearings of many of the cases of this disease give it an importance in such lines which no other disease in childhood has.

Phlegmonous vulvo-vaginitis, as it is usually seen, is due to traumatism. The traumatism may be accomplished in the greatest variety of ways. It may be self-inflicted, or result from accident, or be due to intentional violence at the hands of others. According to Vogel (*Lehrbuch der Kinderkrankheiten*, 1880, p. 431), the gangrenous condition may accompany or follow typhoid fever, diphtheria, measles, smallpox, and scarlet fever. We should expect such a condition to occur, if at all, among children who are poorly nourished and badly cared for, like that analogous condition, *noma*, which sometimes effects the side of the mouth. Fortunately, the condition is a rare one, at least in this vicinity. According to Baginsky, the phlegmonous variety may develop from the catarrhal, but I do not think this would be apt to occur unless a traumatic or infectious element were added.

It is not always easy to differentiate the phlegmonous from the gonorrhœal variety. Indeed the two may coexist, as in cases of rape in which great violence has been used, and in which the criminal suffered with gonorrhœa at the time the assault was made. It is scarcely necessary to dwell upon the course of the disease, which is that of phlegmonous inflammations in general. It is accompanied by great pain, and may result in the formation of pus.

Diphtheritic vulvo-vaginitis—that is, the condition in which a false membrane forms in the vulvo-vaginal region, with more or less destruction of tissue—is by no means limited to diphtheria, although as an essential part of that process it may best be considered in connection with diphtheria. Any morbid condition in which the blood contains an excess of fibrin or fibrinogenous material, may develop diphtheritic vulvo-vaginitis, especially if any abrasion of the skin or mucous membrane exists. It is sometimes seen in connection with typhoid fever and scarlet fever (Baginsky), and Vogel has seen it most frequently during and after epidemics of measles, especially in the damp and crowded dwellings of the poor. It necessarily results in gangrene, to a greater or less extent, and among the illy nourished children of the poor, with bad hygienic surroundings, it means a septic condition which will be likely to have a fatal issue.

As to the question of treatment, whatever be the variety of vulvo-vaginitis, the treatment resolves itself into antisepsis and cleanliness, and perhaps it may some day be demonstrated that these are identical terms. It is not designed to convey the impression that the treatment should be exactly the same in all the varieties of the disease, for any one with even a limited experience knows that the same substances do not produce the same results in all cases. The personal individuality factor enters every therapeutic equation, and this, alas, is often very deceptive and spoils our calculations.

I have seen cases of vulvo-vaginitis in which the patients were apparently in robust health, but this is not the rule, and we must not approach this subject without premising that something is to be given to affect the general condition.

Whether there be coexisting acute disease, or the common constitutional vices, scrofula, rhachitis, or syphilis, the hygienic surroundings are first to be made as favorable as possible, and then the substances which, for want of a better name, are called tonics are to be liberally administered. Whether the choice be iron, mercury, the iodides, or the vegetable bitters, they are too well known and appreciated to require more than a passing notice. I believe there are none of these cases which would not do well by the seashore, and one of the greatest blessings of modern times to children are the *sani-*

taria which have been established at home and abroad for sick children, by the sea. If these could be multiplied manifold, how changed would be the statistics of infantile mortality and morbidity.

For local treatment cleanliness is a *sine qua non*, and yet it is often impossible to impress upon mothers the importance of so cleansing the entire tract involved that recovery can take place. During the stage of acute inflammation, intravaginal injections cannot be given. This would appear to be self-evident in the phlegmonous and diphtheritic varieties, but they are equally contraindicated in the gonorrhœal variety. When the acute symptoms have subsided, a small well-oiled nozzle attached to a fountain syringe is to be introduced within the vagina at least two inches, twice daily, and a gentle current of water at a temperature of 95° to 100° F. allowed to flow in and out for five to ten minutes. Simple boiled water is sufficient for thorough cleansing, but there is no objection to using instead mild solutions of carbolic acid, boric acid, sublimate, salicylic acid, or chloride of sodium. I do not think that these antiseptic solutions add materially to the efficiency of the injections when properly given, and it must be remembered that the epithelium in these cases is exceedingly tender, and that violence will only be likely to increase the inflammation. Most children will resent this treatment, but if a pad of absorbent cotton suitably moistened with a five per cent. solution of cocaine be first applied to the external genitals for five minutes, the injections may be made painlessly.

In the catarrhal and gonorrhœal forms, two drachms of a two per cent. solution of nitrate of silver should be injected into the vagina every other day, excess being carefully wiped away with small pledgets of absorbent cotton. The external genitals should also receive similar applications with a soft brush or pledget of absorbent cotton at the same time. In the intervals a pad of absorbent cotton, which has been moistened with a mixture of bismuth and glycerine (1 : 8), should be placed against the external genitals and secured with a T-bandage. Circumstances will indicate the frequency with which this should be changed.

If the urethra and bladder become involved, mild alkaline or simple emollient diuretics should be given. With children it is not usually well to use local applications, nor are they usually indicated to these organs.

As these means of treatment which have been referred to will usually suffice if carefully employed, it is deemed superfluous to mention other possible systems of treatment. Should pus form in the phlegmonous variety, the usual principles of antiseptic surgery are applicable. Diphtheritic and gangrenous tissues must, of course, be removed as soon and as carefully as possible, and I know of no antiseptic dressing which is less irritating in such cases than the bismuth and glycerine mixture, or even bismuth alone.

159 EAST THIRTY-SEVENTH ST.

OBSERVATIONS ON THE UNITY OF PHTHISIS AND TUBERCULOSIS.[1]

BY G. C. HUBER, M.D.,
ASSISTANT DEMONSTRATOR OF ANATOMY IN THE UNIVERSITY OF MICHIGAN.

DR. AUSTIN FLINT, the author of the article on "Phthisis Pulmonalis," in *Pepper's System of Medicine*, introduces his discussion on the pathology of pulmonary phthisis in the following words:

"There are two distinct varieties of morbid products in cases of phthisis—namely, the miliary granulations and the infiltrated deposit formerly distinguished as crude tubercle."

And then he further states that "histological investigations have failed to establish an essential distinction between the two varieties. The fact that they are so constantly associated shows some close pathological connection."

Dr. Payne, in his work on *General Pathology*, published last year, makes the following statement in speaking of these diseases:

"Tuberculosis of the lungs, or pulmonary phthisis, is by far the most common disease. Here we recognize two forms, distinguished by the manner in which the poison is introduced into and distributed through the organ."

He further states, that "we have two chief forms of tuberculosis, ordinary phthisis and infective tuberculosis; these forms may be combined, the latter being developed out of the former or even *vice versâ*."

Dr. Bristowe, in the latest edition of his work on *The Theory and Practice of Medicine*, holds the same views.

As these may be taken to represent the most modern views on this subject, I undertook, under the direction of Prof. Gibbes, an investigation into the appearances presented by the lungs of those cases which he had in his laboratory. They were twenty-one in all.

The methods pursued in the investigation were the following: Portions were taken from various parts of each lung, sections cut from these, and a large number stained, mounted, and examined. On comparing the appearances found in these cases, together with the clinical histories, they naturally resolved themselves into the following classification: Six were cases of acute miliary tuberculosis; nine were cases of tuberculosis; one a case of caseous phthisis; and five were fibroid phthisis.

The first six cases come under the head of acute

[1] Read before the Michigan State Medical Society, May 9, 1889.

miliary tuberculosis, because the duration of the disease was from two to four weeks and the lungs were studded with miliary tubercles. These six cases did not all present the same appearances under the microscope, although to the naked eye they were identical, and their clinical histories were very similar. In three the tubercle consisted of a reticular fibroid tissue, having one or more giant cells in it and the larger ones having a necrosed centre. In the three others the tubercle contained no structure, but were merely masses of broken-down caseous material. Every section showed the same structure, and in no instance, out of the very large number of sections examined, were these two forms combined. In those lungs where the formation was tubercular, every tubercle presented the reticular formation. In those lungs containing caseous tubercles, each one consisted of a mass of disintegrated amorphous material.

The next nine cases come under the head of tuberculosis, from the fact that the disease had existed for periods varying from eighteen months to three years, and the lesions in the lungs were those of reticular tubercle. The appearances varied very much in the different cases; all the lungs contained cavities varying in size and distribution.

But in those parts of the lungs where the disease had not advanced far enough to form a cavity the structure could be readily made out. It consisted of aggregated reticular tubercles with necrosed centres. The structure of these was identical with the reticular tubercles already described in acute miliary tuberculosis.

One case came under the head of caseous phthisis from the fact that the disease (although the history in this case is not perfect) was known to have existed nine months before death, and all the morbid changes in the lungs were those of caseous degeneration. More than two hundred sections of these lungs were examined and in not one of them is there the slightest trace of any reticular formation. They all show masses of broken-down material, varying in size, and in some parts cavities were formed in these.

The remaining five cases come under the head of fibroid phthisis, on account of the long duration of the disease, the contracted condition of the lungs, and the large amount of fibrous tissue they contained. In four of these cases it was evident that the fibroid change had been set up by the consolidation of croupous pneumonia, which had not undergone resolution. Small tracts of the lungs showed the typical appearances presented by croupous exudation, the fibrinous coagulum in the air cells, the walls of the air vesicles remaining, but all being in a necrosed condition. Some larger tracts had broken down and formed cavities.

The fifth case was that of a woman aged seventy, and there was no history to show what had caused the fibroid change in the lungs, but from the microscopical appearances it was evident that the case was a very chronic one, and the induration had been going on for a long time. From these cases I will leave out the last five; namely, those of fibroid phthisis, as they do not bear directly on the subject of this paper. This will leave sixteen cases, which will come directly under the heads of tuberculosis or caseous phthisis, and which should, according to the authorities I have already quoted, show reticular tubercles or caseous masses indiscriminately mixed.

That this is not the case I have abundant proof in the large number of sections examined, and I can positively state that no section of any of these lungs showed appearances which gave the slightest difficulty in placing it under one or the other of these heads. The two forms never occurred in the same lung. Now the question I wish to put is this: Could I take sixteen cases of lung diseases without the slightest selection and find that they all presented distinct features, either of caseous degeneration or tubercular formation, which features were in no instance intermixed, if the statements made in the before-mentioned text-books were correct?

This seems to be such an important question that I have ventured to bring it before the Society as a matter which ought to receive further investigation.

OBSERVATIONS ON SULPHONAL.

BY C. W. KAVANAUGH, M D.,
OF GAINESVILLE, TEXAS.

SULPHONAL seems destined to occupy a stable and prominent place among the hypnotics. The reports concerning it have so far, for the most part, been favorable, and I have noted in reading but two cases of poisoning reported from its use. The details of these were meagre. One was a morphine-eater suffering with nervous prostration. Ataxia was present but did not last long. In experiments with dogs ataxia was constant, but this is the first case where it was manifest in the human. The other case was in a person affected with chronic myelitis accustomed to the nightly use of chloral. Sulphonal being substituted produced an exanthem lasting two days. Antipyrin caused the same in a sister of patient. Both cases recovered without any special treatment.

I desire to give a brief report of three cases illustrating some of its properties.

CASE I.—Male, aged thirty. I was called to see him in the beginning of a severe attack of enteralgia. He was suffering with acute pain, vomiting continually. The patient having abstained from the use of morphine for over a month and not wishing to revive his old habit, I concluded to try

sulphonal. I administered thirty grains, which were retained, and in twenty minutes patient was asleep. Sleep lasted six hours. Patient was drowsy for half a day, but expressed himself as feeling well.

Case II.—Male, aged forty, came to me seeking relief for a severe headache the result of alcoholic excess. I prescribed forty-five grains of sulphonal. He went to sleep in twenty-five minutes and slept seven hours. No pain in the head on arousing. This patient had used morphine to excess for years.

Case III.—Female, aged thirty-five, had been a great sufferer for several years with "bilious headache," having two attacks each month. The pain was very acute and relief could only be obtained by the inhalation of chloroform. During these attacks the stomach would retain nothing. Two months ago I administered at the beginning of one of these attacks thirty grains of sulphonal. Sleep followed in twenty minutes, lasting five hours; some pain still remaining, I gave fifteen grains more. This relieved the pain, but produced no sleep. Drowsiness lasted one day. Since this attack patient takes fifteen grains on manifesting symptoms of her trouble and has so far succeeded in aborting attacks. This patient, too, was addicted to the morphine-habit.

I have selected these cases out of many in which I have used sulphonal, on account of their addiction to the morphine-habit, as it has been stated that sulphonal has no effect during abstinence from morphine in those addicted to the morphine-habit. This is in direct contradiction to my own experience and that of others to which I will refer.

Dr. W. H. Flint, of New York, finds the effect of sulphonal particularly good in patients who had previously been addicted to the use of opium and other hypnotic drugs or were suffering from insomnia due to the withdrawal of these remedies; and Dr. Ruschugh Jena has obtained excellent results in the case of a morphine-eater.

Ott, of Prague, relates a case of hypochondriasis with arthritic disposition and temporary arhythmia of the heart, and the patient was accustomed to the injection of morphine. He slept well after the administration of thirty grains of sulphonal and the arhythmia always ceased a few minutes after its use.

The results from sulphonal in insane asylums has been exceptionally good. It has been found to be of special benefit in cases of self-pollution. I have used sulphonal in typhoid fever for nervousness and to produce sleep, and it met these troubles better than any agent I have ever used. I noticed no effect on the circulation or temperature.

In rheumatism it relieves pain much better than antipyrin.

In comparison with chloral and the modern remedies paraldehyde and urethan, the following advantages are apparent. Unlike chloral it does not depress the heart or irritate the stomach, but seems to have a sedative influence on the latter, and it is very easy to take, being in this respect much superior to paraldehyde, which is very disagreeable and its nauseous taste may continue long after its administration. Urethan is very uncertain in its action, and the reports concerning it indicate that it possesses very little virtue.

Sulphonal is a reliable hypnotic, has anodyne and analgesic properties. Its effects are quick and certain and it is practically free from bad after-effects. The majority of patients express a feeling of well-being after its use.

As regards the dose, I find thirty grains sufficient to produce sleep. It is odorless and tasteless, and therefore can be administered in powder. In repeating the dose it must be borne in mind that it is eliminated very slowly.

MEDICAL PROGRESS.

Hydracetin, a New Antipyretic.—Dr. Paul Guttmann, in the meeting of the Berlin Medical Society of May of this year (see report in *Wiener med. Presse*, No. 21, 1889), reported the results of his investigations with hydracetin, a new antipyretic. The drug is a white powder, odorless and almost tasteless, soluble in water only in proportions of one to fifty, however easily soluble in alcohol. Four to eight grains injected into a rabbit's peritoneum caused the animal's speedy death. Autopsy showed that death was caused by the powerful reducive and absorptive effect the drug had on the oxygen in the blood. Doses of one and one-half to two grains a day were sufficient to reduce the temperature 2° to 3½° F., and to cause profuse perspiration. One dose would keep the temperature down for five or six hours, after which it rose again with moderate rapidity. Guttmann has used the drug in a large number of cases of typhoid fever, phthisis, scarlatina, erysipelas, acute miliary tuberculosis, septicæmia, and also in eight cases of typical and severe multiple acute articular rheumatism. The action of hydracetin was always the same and accompanied with positive results. In acute articular rheumatism doses of less than a grain gave almost immediate relief to the pain which lasted for several hours. Hydracetin found further use in two cases of psoriasis in which a salve containing ten per cent. of the drug was used for less than a week, complete recovery resulting. In two cases of sciatica one-grain doses of hydracetin had a most happy anodyne effect, which lasted for several hours. No unpleasant accompanying or after-effects were ever observed to follow its use, further than a slight and temporary pallor of the face. Guttmann is of the opinion that not more than one and a half or two grains should be given daily. In cases of severe fever, such as typhoid, the above amount should be given in one dose, or in two doses an hour apart from each other. In articular rheumatism two daily doses of about three-quarters of a grain each seemed to be followed by the best results. The daily administration of one and a half or two grains should not be continued for over three days; after an interval, however, its use may again be resorted to. The

drug is equally valuable either as an antineuralgic or an antipyretic.

Petroleum Soap for Itch.—The following is recommended by DR. H. EMERY, of Paris, in the *Revue gén. de Clin. et de Thér.*, May 16, 1889, as most efficacious in obstinate cases of itch:

℞.—Petroleum	. . . .	50 parts.
White wax	. . . .	40 "
Alcohol	. . . .	50 "
Soap	. . . . .	100 " —M.

Rapid Cure of Chorea by Antipyrin.—According to DR. LEGROUX, in the *London Medical Recorder*, May 20, 1889, fifteen-grain doses of antipyrin, given three times a day, is a most speedy and effectual remedy in chorea. He has cured six cases within a month. Legroux's experiences are substantiated by GRIM, in the *Centralbl. für Nervenheilk.*, page 148, 1889, and also by LILIENFELD, in the *Centralbl. für die med. Wissenschaften*, page 784, 1887, who have also reported similar favorable cases.

Grafts of Frog's Skin in Chronic Ulcers.—In the *Rüsskaia Meditzina*, DR. FEODOSY NESTEROVSKY, of Bratzlav, speaks favorably of frog's skin-grafting, a method which was first proposed by Dr. Allen in 1884, and subsequently practised successfully by Drs. O. V. Peterson, of St. Petersburg,[1] Perez, Baratoux, Dubousquet-Laborderie, etc. Dr. Nesterovsky relates four cases of old-standing, intractable, extensive, and deep ulcers of the leg, foot, and thigh, where, after all ordinary means had failed, the transplantation of grafts of frog's skin was invariably followed by a permanent healing in from nine to fourteen days. Dr. Nesterovsky takes an ordinary water frog and keeps the lower portions of its body immersed in a sublimate solution (1:1000) for five minutes; then he pinches up a piece of skin on the abdomen with forceps, and cuts out as many grafts as are required, each the size of a finger-nail. Having washed the pieces as well as the ulcer with a 4 per cent. solution of boracic acid, he carefully places the grafts on the granulating surface, and covers the part with a layer of boracic gauze and a piece of tow, fixing the whole with wax-cloth and a starched gauze roller. The dressing is changed and the ulcer washed first on the third or fifth day. The writer summarizes his experience as follows: 1. In all cases of extensive and badly cicatrizing ulcers, skin-grafting is indicated. 2. Skin which is quite free from glands and hairs is most suitable for the purpose. 3. The frog's skin completely satisfies those conditions. 4. The method is simple, safe, easily used everywhere, cheap, and most effective. This method of grafting has, we believe, been tried with success by Mr. Stanley Boyd, of Charing Cross Hospital.—*British Medical Journal*, June 1, 1889.

The Effects of Splenectomy.—In the last congress of Italian surgeons, which was held in Bologna during May, 1889 (reported in the *Wiener klin. Wochenschrift*, May 23, 1889), the subject of extirpation of the spleen gave rise to most active discussion. DR. CECI, of Genoa, related a case of splenectomy, which was followed by swelling of the thyroid gland, fever, and emaciation, also complete hypertrophy of the tonsils. Later the general condition of the patient improved somewhat. The tonsils, on account of their condition, were excised. After this the thyroid swelling gradually disappeared.

DR. D'ANTONA, of Naples, reported a case of splenectomy which he performed in a child aged three. The patient had been suffering from a remitting fever of a severe and chronic type, and which no treatment seemed to alleviate. The spleen was greatly enlarged. After excision the wound healed by first intention, but the symptoms of fever did not abate. Later gastro-intestinal complications manifested themselves and the child died. Upon examination the spleen was found to contain large numbers of an as yet undescribed bacterium.

D'Antona does not consider the child's death due to the operation, and states that in similar cases he would certainly consider extirpation of the spleen indicated.

Hemostatic Collodion.—The following formula for hemostatic collodion, which is given by DR. PARESI, in the *Revue de Thér. méd.-chir.*, May 15, 1889, will be found very valuable as an application for abrasions and superficial wounds:

℞.—Collodion	. . . . .	100 parts.
Phenic acid	. . . .	10 "
Tannin } Benzoic acid }	. . .	āā 5 "

Apply with a camel's-hair brush.

Pilocarpine in Traumatic Tetanus.—DR. L. CASSATI, in the *Journal de Méd. de Paris*, May 26, 1889, reports three cases of traumatic tetanus which he has cured by heroic doses of pilocarpine given hypodermically. Since then he has experimented upon rabbits, inoculating them with the bacilli of tetanus and under the pilocarpine treatment only two out of nine died. The drug acts very quickly, all symptoms of tetanus disappearing in a few hours. Subsequent recovery is speedy and complete.

Creasote in Flatulency.—The antiseptic properties of creasote render it valuable in cases of flatulency and indigestion. DR. PEPPER, in the *Gazette hebd. de Méd. et de Chir.*, May 21, 1889, prescribes it in combination with alkaline salts, and gives the following emulsion:

℞.—Creasote	. . . . .	gtt. x.
Bicarbonate of soda	. . .	ʒij.
Pulverized gum	. . . .	q. s.
Water	. . . . .	fʒv.—M.

Dose, a tablespoonful an hour after meals. If the stomach is in an atonic condition and the gastric secretions are scanty, the following formula may be used to advantage:

℞.—Pepsin	. . . . .	ʒj.
Creasote	. . . . .	gtt. x.
Sub-carbonate of bismuth	. .	ʒj. —M.

Divide into thirty capsules. Dose, one, an hour after each meal.

Treatment of Angina Pectoris.—PROF. HUCHARD, in addressing the Hospital Medical Society of Paris, stated that, in his opinion, it was not the pain of angina pectoris that caused the profound distress of the patient, but rather the increased tension of the arteries. This, then, must be dealt with primarily. Preparations of iodine,

[1] Riforma medica, April 11, 1889.

used for a long period, nitrite of amyl, and nitroglycerine give good results.—*Deutsche med. Wochenschr.*, May 23, 1889.

Thiol as a Substitute for Ichthyol.—The Berlin correspondent of the London *Provincial Medical Journal*, in writing to the number of that journal appearing June 1, states that ichthyol has found a rival in thiol, a new product of chemical synthesis, obtained by artificially sulphuretting unsaturated hydrocarbons, and charging these with 10 per cent. of sulphur. Chemical and therapeutic researches prove its exact identity with ichthyol. Thiol consists of a brown fluid of the consistency of syrup; it is completely soluble in water, is totally inodorous, and has, therefore, a decided advantage over ichthyol. There exists also a dry thiol, which has two and a half times the strength of fluid thiol, otherwise having the same properties as the latter. Thiol is used like ichthyol in the following diseases: Acne, acute and chronic rheumatic arthritis, other rheumatic affections, contusions, decubitus, eczema, erysipelas, neuralgia, ischia, leprosy, frost-bites, prurigo, pruritus, ulcus cruris, burns, and scalds. On the initiative of Schweninger, thiol was tried at the Charité Clinic of Berlin, and Dr. Reeps reports on these trials in a very favorable light, as does also Dr. Buzzi, whose opinion is based on an even more extended clinical experience.

Dr. Reeps states that it may safely be concluded that thiol, externally applied in skin diseases, has positively the same effect as ichthyol. As their effect in these instances is identical, it may also be assumed that thiol will prove equally efficacious in other diseases where ichthyol has been employed. Reeps has taken internal doses up to two and a half grammes without discomfort or disturbance of the stomach; he believes, therefore, that it is comparatively harmless. It has been asserted lately that this is not the case with ichthyol, but he ascribes the adverse physiological effects of ichthyol to its obnoxious taste and odor, and these are entirely eliminated in thiol. He does not consider there is any further doubt that thiol and ichthyol are two exactly identical substances, and that thiol will serve to replace ichthyol when the natural sources of the latter remedy become exhausted; even now the discovery may be recognized as a great boon, which makes us independent of nature's supply of this valuable remedy. The following are the usually prescribed formulæ:

℞.—Thiol . . . . . ʒj.
Vaselin . . . . . ʒj.
Lanolin . . . . . ʒj.—M.

Make into ointment. S. For external use.

℞.—Thiol sicc. . . . . gr. ij.
Pulv. glycyrrhizæ . . . . gr. ij.
Glycerin tragacanth . . . . q. s.—M.

For one pill. S. One pill to be taken three times a day.

℞.—Thiol sicc. . . . . ʒj.
Zinc. oxid. . . . . ʒij.
Amylum . . . . . ʒj.
Talc . . . . . ʒij.—M.

For powder. S. The affected parts to be dusted with this powder.

Salol as a Dressing.—At the last meeting of the Hunterian Society of England, reported in the *Provincial Med. Journ.* of June 1, Mr. Corner exhibited several cases illustrative of the antiseptic power of salol (salicylate of phenol) as a dressing for wounds after the pads had been rendered aseptic by a 1:20 solution of carbolic acid. Salol has a pleasant odor, and could be used freely without fear of poisoning or irritating, and when dry formed a hard but friable surface. A case was shown where the wound was dressed with salol and left untouched for a month, and remained sweet.

Wiring the Phalanges.—Prof. Lewis, of the Wabash Hospital, reports in the *Kansas City Medical Index* for May, a case of ununited fracture of the first phalanges of the first and second fingers. After all other modes of treatment had failed, the fragments were wired together. The result was speedy and perfect union.

Treatment for Baldness.—Dr. E. Besnier says that the falling out of the hair may be checked, and a new growth started by the following treatment. The hair should be cut short and a mild sinapism or rubefacient applied to the scalp; then every five days the following lotion is to be applied:

℞.—Acetic acid } . . . āā q. s.—M.
Chloroform }

The above should be used cautiously, as it is an irritant, but stimulates the hair powerfully. In connection with the above, the following pomade should be used:

℞.—Salicylic acid . . . . gr. xv.
Precipitate of sulphur . . . ʒjss.
Vaseline . . . . . ʒv.—M.

This pomade should be applied fresh every morning, the scalp previously having been well washed. Fatty substances retard the growth of the hair, and should not be used.—*Journal de Méd. de Paris*, May 12, 1889.

Ephedrin and Pseudo-ephedrin.—At the Medical Congress of Bologna, Dr. Wreise reported the results of a series of experiments with the two alkaloids of the Ephedra vulgaris, ephedrin and pseudo-ephedrin. The first investigations with this drug were made by Dr. K. Miura, of Tōkyō, Japan. Wreise's results show that the action of ephedrin is rather uncertain; that, however, of pseudo-ephedrin is more constant. The latter acts as a strong mydriatic; a few drops of a ten per cent. solution will produce enlargement of the pupil lasting seven to eight hours. The action of the drug takes place in about half an hour after it has been dropped into the eye. Neither accommodation, refraction, nor sensibility of the conjunctiva or cornea were in any wise influenced by the drug.—*Wiener klin. Wochenschrift*, May 30, 1889.

The Influence of Parenchymatous Injections into the Spleen.—Questions concerning various affections of the spleen, as well as operations upon it, seem to have taken an important part in the Italian Congress of Surgeons held at Bologna, as reported in the *Wiener klin. Wochenschrift*, May 30, 1889. Dr. Beorchia Nigris read a paper on the influence of parenchymatous injection upon enlargements or tumors of the spleen. There was an extensive discussion regarding the relative value of different fluids for injection. Nigris said that he had tried water, Fowler's

solution, weak solutions of quinine and strychnine, etc., and had found that equally good results were obtained by injections of water as by any other substance. In all cases he observed the formation of connective tissue at the seat of the injection. This tissue in contracting or shrinking caused a decided decrease in the size of the spleen. Nigris is of the opinion that this phlogistic process is entirely independent of the nature of the fluid injected.

A Saline and Chalybeate Tonic.—DR. AUSTIN FLINT, in writing to the *New York Medical Journal*, states that after long and careful investigations, he has found the formula given below to be a most efficient chalybeate. Its action is most marked in cases of anæmia, loss of appetite, etc.:

℞.—Chloride of sodium	℥iij.
Chloride of potash	grs. ix.
Sulphate of potash	grs. vj.
Carbonate of potash (Squibb)	grs. iij.
Carbonate of soda	grs. xxxvj.
Carbonate of magnesia	grs. iij.
Precipitated phosphate of calcium	℥ss.
Carbonate of calcium	grs. iij.
Ferri redacti (Merk)	grs. xxvij.
Carbonate of iron	grs. iij.—M.

In capsules, No. 60.

Sig.—Two capsules three times a day, after eating.

This formula is put up in the form of compressed tablets by Frazer & Co., of New York, also as tablets made by Caswell, Massey, & Co., 1121 Broadway, and as sugar-coated tablets, made by Wanier & Imgard, 1322 Broadway, New York.

Dr. Flint gives the preference to the sugar-coated tablets, as the others sometimes produce slight nausea.

Iodides in Cardiac Affections.—DR. MASCAREL, in an article in the *Revue gênêr. de Clin. et de Thêr.*, May 30, 1889, says that he has found six to seven-drachm doses of iodide of sodium and iodide of potassium, given twice daily, exert a most beneficial action in cases of valvular endocarditis, especially when of a rheumatic nature. In conjunction with this treatment a strict milk diet should be enforced.

Phenol in Whooping-cough.—DR. ROTHE, in the *Revue gênêr. de Clin. et de Thêr.*, May 30, 1889, says that he has found phenol, in the following formula, most efficient in whooping-cough. Under this treatment the disease seldom lasts two weeks:

℞.—Phenic acid } Alcohol }	āā	grs. xxxj.
Tincture of iodine		gtt. xx.
Tincture of belladonna		f℥j.
Peppermint water		f℥iijss.
Syrup of opium		f℥ss.—M.

A half teaspoonful should be taken every two hours until the symptoms decrease in severity.

Antipyrin in Labor.—PROFESSOR PINZANI, of Bologna, says the *Wiener klin. Wochenschrift*, May 30, 1889, has found, by numerous experiments, that antipyrin considerably lessens the severity of labor, while it does not retard its natural course. When given hypodermically its action is manifested in about two hours, but if given by the mouth no relief or ease of pain is noticed until after four or five hours.

Dyspeptic Insomnia.—The following prescription, given by DR. THONIN, in the *Revue de Thêr. mêd.-chir.*, May 15, 1889, is claimed by him to be most effectual in relieving the sleeplessness which so frequently accompanies certain forms of dyspepsia:

℞.—Syrup of coca	℥ijss.
Hydrate of chloral	℥ij.
Bromide of soda	℥j.
Tincture of chloroform	gtt. xx.

Three doses, of a dessertspoonful each, should be given one hour apart from each other. No gastric irritation has been observed to follow its use.

Treatment of Granular Lids.—In writing to the *Kansas City Medical Index* for May, 1889, DR. F. M. SCOTT states that he has found the following method of treatment of granular lids most efficacious even in most severe and obstinate cases accompanied with pannus. The lids are painted with a weak solution of nitrate of silver (five grains to the ounce of water) four times a week, and immediately after washed out with a weak solution of salt and water. Five drops of the following should be applied daily by the patient:

℞.—Boracic acid	grs. xv.
Tannic acid	grs. x.
Glycerine	℥jss.
Rose water, q. s. to make	℥j. —M.

The Alkaloids Used in Eye Diseases.—The alkaloids most commonly used in ophthalmology, such as atropine, duboisine, hyoscine, eserine, etc., are usually applied in the form of sulphates. DR. GALEZOWSKI, in *L'Union Médicale* of June 8, 1889, maintains that these salts contain an excess of acid, and when used in the form of lotions or ointments quickly undergo decomposition, the acid being liberated. Their use in this form is, of course, very irritating to the eye. Galezowski therefore suggests that the sulphuric acid be replaced by boric acid and borates be employed instead of sulphates. The borates are far more stable and less irritating. Borate of atropine acts somewhat slower than sulphate of atropine, but it is far less irritating, less painful, and its action longer. Borate of cocaine is not so rapid an anæsthetic as the other salts commonly used, but it is equally as effective.

Chromic Acid for Perspiring Feet.—The Medical Department of the Prussian War Office reported last year the results of a series of experiments regarding the value of chromic acid in sweating feet. The drug was used in over eighteen thousand cases, all of which were reported.

It is best used in a five per cent. solution, and should be applied with a camel's-hair brush, the feet having been previously thoroughly washed and dried. The acid seems to harden and strengthen the skin; the moist and reddened portions become dry and smooth-looking, and the fetid sweat quickly disappears. In many cases three or four applications effected a permanent cure. Increased endurance for marching was immediately observable.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JULY 6, 1889.

THE TREATMENT OF UTERINE TUMORS BY ELECTRICITY.

IT is but a few weeks since prominent neurologists of New York, in a discussion at the Academy of Medicine upon the application of electricity to the nervous system, expressed decided scepticism as to its lasting benefit for many of the conditions for which it is now used, and even showed an eagerness to banish one form of it—Franklinism—to a limbo whence it could not be recalled. These reactionary views did not proceed from inexperienced nor unthinking men, nor are we willing to believe that they signified that electricity as a therapeutic resource is to be relegated to the quacks. Such is the status, however, in the evolution of electricity as a therapeutic agent for nervous diseases.

A somewhat similar scepticism prevails in regard to uterine electro-therapeutics, in no department of which have more substantial results been obtained than in connection with myomata or fibro-myomata or fibroids, as they are commonly called; at least such is the assertion of the advocates of this method of treatment. Attempts at treatment with this agent were made long ago, and it will not do to ignore or belittle the efforts which were made by Kimball and Cutter, and Freeman, imperfect as they may have been in the light of the present attainments; nor the efforts of Sir James Simpson, which were still more imperfect, according to the testimony of Thomas Keith, who participated in them, and which accomplished no benefit, but rather did harm. It has remained for Apostoli to systematize and perfect a method of treatment for uterine fibroids which, in *skilful hands*, can be fairly called comparatively safe, comparatively painless, and efficient. This is the testimony of four such witnesses as Sir Spencer Wells, the Keiths—father and son, and Playfair.

The proposition, and we may say the doctrine, of Apostoli may be formulated in the following terms: Given an uterine fibroid tumor, large or small, with its accompanying inconveniences and perils—which include discomfort, pain, bleeding, weakness, and inability to attend to the customary duties of life—these may all be relieved, and the tumor may be reduced more or less in size, by the use of the galvanic current, with an intensity varying from 100 to 350 milliampères, from five to twenty minutes two or three times a week for a period of two or three months or more. Extraordinary precautions are required as to thorough cleanliness of all electrodes used, and the antiseptic principle is applied to the treatment as far as possible. The galvanic current may be introduced into the tumor through sharp-pointed electrodes which puncture the tumor, or one electrode may be introduced into the uterus or vagina, and the other laid upon the abdomen, the latter being very large, imbedded in wet clay, and adapted to high intensities and considerable diffusion. The other details as to electrodes of particular kinds, and other necessary instruments, need not concern us now.

The credibility of Apostoli's assertions is vouched for by witnesses of the highest respectability, including those whose names have been given. Furthermore, the gentlemen mentioned are entirely competent as surgeons and gynecologists to express an opinion. They have all been to Paris, have seen Apostoli's work, have learned his methods, and have made practical application of them themselves. What is still more remarkable, to one of them the world is more indebted than to any other man for developing abdominal surgery when its advocates were few and timid, and he has practised it with distinguished success for a considerable portion of a long life; while another of the same group has taught the world the possibilities of abdominal surgery by mortality statistics which are susceptible of little if any improvement. Keith—the successful surgeon, the man whose record in hysterectomy stands unrivalled—pleads for a cessation of hysterectomy for fibroid tumors until electricity has had a

thorough trial. This seems like a fair proposition, and in the face of such facts as the necessarily high mortality by the knife, even at the hands of the most skilful surgeons, it is incumbent upon gynecologists to make a fair, searching, and unprejudiced investigation into the merits of the case.

On this side of the Atlantic, opinion as to the value of this treatment has varied about as it has in England. It has its pronounced advocates who have done good work. Among them may be mentioned Lapthorn Smith of Montreal, Martin of Chicago, Engelmann of St. Louis, and others. Engelmann has even laid the subject, with clearness and enthusiasm, before the assembled gynecologists of Berlin, and this is the best way to lay an enemy's country under tribute. Acrimonious dispute has also not been wanting.

It is idle to expect that accident will never follow this treatment. He is foolish who would assert it, and he is more foolish who would believe it. We entirely disagree with those who think that electricity may be used in gynecology without much knowledge of its physics, at least safely and efficiently. If the best results are to be obtained, an understanding of the means to be used is as indispensable as in any other case in which the best results are sought.

Concerning the way in which the galvanic current acts in fibroid tumors, which has excited so much discussion, profitless as it seems to us, the most that can be said is that it causes impairment of nutrition. The results demonstrate that fact clearly enough, and all the speculations in regard to polar action, electrolysis, diffusion of current, etc., do not change or affect it.

A practical drawback to this method of treatment is the expense of the necessary apparatus. This will deter many from making the requisite trial of it, but it is to be hoped that it will not weigh with those who are constantly being called upon to treat fibroid tumors. What is now needed for the formation of a correct conclusion of the value of electricity in the treatment of uterine fibroids, is the record of experience of a number of careful observers.

THE TEACHERS OF HYGIENE IN EUROPEAN UNIVERSITIES.

THE University of Kiel has inaugurated a professorship of Hygiene, and Dr. Bernard Fischer has been appointed to the chair. There now remain only two Prussian Universities—those of Bonn and Königsburg—without such chairs. Dr. Fischer was one of Professor Robert Koch's pupils and accompanied him on that memorable journey into Egypt and India which resulted in the discovery by Koch of the bacillus of Asiatic cholera. Another companion on that voyage was Dr. Gaffky, now Professor of Hygiene at Giessen. Other pupils of Koch occupy the same department of instruction in other universities, as Dr. Gärtner in Jena, Dr. Löffler in Greifswald, Dr. Hüppe in Wiesbaden, Dr. Becker in Leipsic, Dr. Fränkel in Berlin, and Dr. Frank in Naples. These are all members of the younger generation of instructors and are adepts in the laboratory methods of Koch. Dr. Fischer's original work has been exerted in two directions chiefly, one in the application of bromine to disinfection, another in the study of the phosphorescence of the sea.

DR. HENRY C. COE has been appointed Professor of Gynecology at the New York Polyclinic, to fill the vacancy occasioned by the death of Dr. James B. Hunter.

A CONSIDERALE space has been given by the public press to the newly proposed plan of disposal of corpses by desiccation or mummification. The promoters of the plan claim, with no little show of reason, that it has all the advantages that pertain to cremation, and has one manifest advantage over the latter in that the possibility of the proof of crime is not destroyed by the combustion of the body. The theory of the process implies that the gases only—given off by decomposition—shall undergo combustion, currents of dry air being in constant motion over the bodies placed under this method, sometimes called the "new mausoleum plan."

WE are informed that a French translation of Dr. Senn's work on *Surgical Bacteriology* will be issued shortly by a Paris publishing house.

WE learn from a German contemporary, that Dr. W. Roeventhal, who has recently been studying the influence of salol upon the cholera bacilli, in the Cornil laboratory in Paris, has received a special commission from the French Government to go to Tonkin to continue his experiments on the human subject—that is, to test the drug in the disease itself. High rank in the French Marine Service has been conferred upon him, and he has been made entirely independent in his actions. The expenses of his researches will be borne by the French Government.

This is the first case of a physician, who is still a German citizen, receiving an appointment of this kind.

ACCORDING to the *London Medical Recorder* of May 20, 1889, no fewer than 1168 human beings were destroyed by snakes in the Bombay Presidency during 1887, and over 300,000 venomous snakes were destroyed.

SOCIETY PROCEEDINGS.

AMERICAN MEDICAL ASSOCIATION.

Fortieth Annual Meeting, held at Newport, R. I., June 25, 26, 27, and 28, 1889.

(Specially reported for THE MEDICAL NEWS.)

GENERAL SESSION.

FRIDAY, JUNE 28TH.—FOURTH DAY.

The Association was called to order by the President, at 10 A.M., and opened with prayer.

DR. W. H. WELCH, of Baltimore, then delivered the

ADDRESS IN STATE MEDICINE,

which will be published in full in a later issue of THE MEDICAL NEWS.

MISCELLANEOUS BUSINESS.

The Section on State Medicine reported that the Committee on Infanticide had made no report, and asked that the Committee be dismissed in accordance with the By-laws.

DR. N. S. DAVIS moved that a committee be appointed to secure excursion rates over the most feasible routes to the International Medical Congress, in Berlin. The motion was carried.

Drs. Pancoast, Surgeon-General Hamilton, A. Nelson Bell, and N. S. Davis were so appointed.

The following were announced as

DELEGATES TO FOREIGN MEDICAL ASSOCIATIONS:

I. N. Quimby, J. W. Jackson, F. J. Lutz, S. E. Solly, J. F. Noyes, J. M. French, A. J. Fuller, E. Cutter, J. H. Knight, I. N. Love, J. M. Matthews, W. C. Wile, W. F. Hutchinson, A. N. Owen.

Delegate to the Canada Medical Association, Dr. P. S. Conner.

THE JOHNSTOWN CALAMITY.

SURGEON-GENERAL HAMILTON offered a resolution expressing sympathy with the unfortunate members of the community of Johnstown, Pennsylvania, and especially with the members of the profession. Also that the Treasurer of the Association be authorized to remit the annual dues of any member residing there.

The Secretary then read the following list of

OFFICERS OF SECTIONS

for the ensuing year.

SECTION OF MEDICINE.—*Chairman*, J. H. Musser, M.D.; *Secretary*, H. McColl, M.D.

SECTION OF SURGERY.—*Chairman*, B. A. Watson, M.D.; *Secretary*, J. B. Deaver, M.D.

SECTION OF OBSTETRICS.—*Chairman*, W. W. Potter, M.D.; *Secretary*, J. E. Hoffman, M.D.

SECTION OF STATE MEDICINE.—*Chairman*, J. B. Hamilton, M.D.; *Secretary*, F. S. Bascom, M.D.

SECTION OF OPHTHALMOLOGY.—*Chairman*, S. C. Ayres, M.D.; *Secretary*, E. J. Gardner, M.D.

SECTION OF DISEASES OF CHILDREN.—*Chairman*, I. N. Love, M.D.; *Secretary*, Dr. Bush.

SECTION OF DERMATOLOGY AND SYPHILOGRAPHY.—*Chairman*, I. E. Atkinson, M.D.; *Secretary*, W. T. Corlett, M.D.

MISCELLANEOUS BUSINESS.

The Secretary, Dr. Atkinson, moved that he be authorized to refer the reports of the Secretaries of Sections, which he had received, to the Committee on Publication. The motion was carried.

The President, Dr. Dawson, through the Secretary, moved that a vote of thanks be extended to the Chairman of the Committee of Arrangements, Dr. Storer; to the Governor of Rhode Island; to the people of Newport, and to the large number of individuals who had materially contributed to the entertainment of the members of the Association during their stay in the city.

Dr. Pancoast, of Philadelphia, responded to the remarks of Sir James Grant at the Thursday session. In conclusion he moved that a vote of thanks be extended to that distinguished gentleman for his presence and good wishes, and that it is the desire of the Association that he may soon again be present at its meeting.

Sir James Grant then expressed his gratitude as well as that of the profession of Canada for the cordial welcome which he had received at the hands of the Association, and for the handsome manner in which he had been entertained during this most interesting meeting of the American Medical Association.

The Association then adjourned.

SECTION OF OBSTETRICS AND GYNECOLOGY.

WEDNESDAY, JUNE 26TH.

(Concluded from page 731.)

DR. A. VANDER VEER, of Albany, N.Y., read a paper on

CONCEALED PREGNANCY: ITS RELATIONS TO ABDOMINAL SURGERY,

based upon a study of seventy cases of abdominal section in which pregnancy existed as a complication which had not been diagnosticated. It was observed that the most eminent operators, as well as those of few opportunities, had made the same error relative to pregnancy. A diligent effort had been made to obtain the histories of reported cases, and the library of the Surgeon-General's Office had been thoroughly searched, in addition to three hundred circular letters which had been sent to surgeons in this country and in Europe.

The results of these researches were tabulated in the author's paper, and though incomplete they contained all accessible literature. Abstracts of ten cases were given, including two which came under the author's personal observation. There were twenty-six cases in which pregnancy was complicated with fibroid tumors,

and no diagnosis had been made. The indications for operation had depended upon a rapidly growing abdominal tumor of obscure character, and great distress on the part of the patient. In the majority of the cases there had been no symptoms of pregnancy. Rapid growth and changes in the consistency of the tumor had been observed in nearly all the cases, yet pregnancy had, in many of them, been unsuspected. Rapid growth *per se* might be fallacious as an evidence of pregnancy, for it might depend upon malignancy or other conditions. Amenorrhœa had been observed in eleven cases, and mammary changes in four. In the earlier months of pregnancy there might be even excessive flowing, such a cause frequently resulting in abortion in cases of fibro-myxoma.

The physical signs of pregnancy, prior to the fourth month, might be obscured or concealed by the presence of fibro-myxoma. The uterine sound had been used in nearly all cases and only served to confirm the erroneous diagnosis. Again, pregnancy might be extra-uterine or in a rudimentary horn of a bi-cornuate uterus. The author did not intend to affirm that the diagnosis of pregnancy prior to the fourth month, as a complication of fibro-myxoma was impossible in all cases, but did believe that the diagnosis was, at best, a matter of presumption, and that it was often impossible when immediate operative interference was demanded. In only three of the reported cases did error occur after the fifth month.

Nine abdominal sections had been classified in which the incision revealed a pregnant uterus alone. Five cases occurred early in the history of abdominal surgery when methods of differential diagnosis were not as well taught and practised as now. Hydramnion as a complication of pregnancy led to abdominal section in two cases. The cases of Doctors Prince and Varian illustrated the utter unreliability of the statements of unmarried women with abdominal enlargement, whatever their reputation for chastity might be. Pregnancy as a complication of ovarian cyst had been frequently met with, and had not always been diagnosticated. In twenty-eight of the collated cases there had been no symptoms, except that in one there had been amenorrhœa. Should there be the slightest suspicion of pregnancy the use of the uterine sound is positively contraindicated, as abundant experience had shown that we had no right to induce abortion before performing ovariotomy.

From the facts which had been obtained the following conclusions were justifiable:

1. From the study of these sixty-eight cases the author was convinced that errors of diagnosis frequently depend upon conditions which make it absolutely impossible to avoid the same diagnostic conclusions should the same conditions recur in other cases.

2. It would seem to be the duty of every operator before making an abdominal incision, to secure by his own efforts or by those of a sufficiently qualified operator, a fully classified written statement of the facts which make up the clinical history of the case, together with the results of the physical exploration made by the operator and his consultants, a formal blank statement being used so that no facts may be omitted. No part of this duty should be delegated to *internes* of hospitals, except under proper supervision.

3. The probable diagnosis should be based upon the physical signs expressed in the notes, corroborated, with few exceptions, as in the case of unmarried and ignorant patients, by the rational signs contained in the clinical history, and not by simple abdominal palpation and "the dim" light of a pelvic examination.

4. Should the slightest probability of pregnancy exist it should be clearly stated to the patient and to her friends.

5. The necessity for operative measures and the consequences of delay or neglect should be carefully stated to the individuals concerned, before obtaining their formal consent to an operation.

6. Every operator should report all such cases *in full*, that the methods of diagnosis may be improved if possible.

7. The profession at large should maintain that pregnancy *may be* absolutely concealed, especially prior to the fourth or fifth month, by other intra-abdominal conditions.

THURSDAY, JUNE 27TH.

The papers of the previous session being, with one exception, concerned with the

PATHOLOGY, OR SURGERY OF THE ABDOMEN,

or its contents, were discussed together. The discussion was participated in by Drs. Polk, Price, Baldy, Hoffman, Parish, Dudley, Gordon, and several others. The following is a brief *rêsumê* of this discussion:

Dr. Johnson had done well in calling attention to the possibility of infection by the bacillus of tetanus after ovariotomy, and operators should not forget that their horses or their stables might be media for this variety of infection. The short list of cases cited by Dr. Johnson was increased by cases mentioned by Dr. Gilman Kimball and Dr. Parvin, all of which would be incorporated in Dr. Johnson's paper.

Concerning accidents to the bladder in connection with laparotomy, it was thought singular by Dr. Price that the mortality should have been great. In general, while there was the possibility of accident even to the most careful operator, as Dr. Jackson had affirmed, it would seem as if the method which is adopted by many operators, of carefully lifting a small portion of the peritoneum or what is believed to be the peritoneum upon a tenaculum or forceps, and isolating it from the underlying structures of whatever character, would be sufficient to enable one to avoid wounding either the bladder, the intestines, or any other structure which one does not intend to penetrate.

No objection was raised to Dr. Parish's classification of pelvic abscess, and it was generally believed that it placed the profession upon the position which was established many years ago by Bernutz and Goupil. Other theories of pelvic abscess, notably those of Emmet and Thomas, were now believed to be untenable, and while some operators might err in regarding the large proportion of these abscesses as due to tubal or ovarian disease, it was certainly true that such disease was the causative factor in very many cases. Areolar abscess, also, was not limited in its etiology to conditions associated with pregnancy, but, as the author of the paper had said, might originate from traumatism or infection.

As to the treatment, the greater number of the disputants believed in laparotomy in most cases, if the abscess were located within the abdominal cavity.

The discussion of Dr. Vander Veer's paper on

CONCEALED PREGNANCY

elicited the narration of a large number of cases in which errors of diagnosis had been made, and showed that even with the greatest care in obtaining histories and in making examinations such errors would occur. It was believed that it did not necessarily reflect unfavorably upon a gynecologist, in the eyes of his colleagues, though it might in the eyes of the friends of the patients, if, after suitable precautions had been taken, a mistake should sometimes be made.

DR. S. C. GORDON, of Portland, Me., reported a

CASE OF EXTRA-UTERINE PREGNANCY,

in which a successful operation had been performed after the rupture of the tubal sac. This was the speaker's second successful case, his first having been operated upon in 1886. The latter was the third successful operation for this condition which had been performed in this country. The history of the case, in brief, was that the patient missed her menstrual periods between the months of February and June, 1888. In the latter month she had two severe attacks of pain and prostration, in which rupture of the sac occurred. She rallied from both of them, and continued in a fair state of health until November, having menstruated the two previous months and also having a profuse leucorrhœal discharge. When seen, in November, by the speaker, she had a small tumor to the right of the uterus, and the condition was diagnosticated as a tubal pregnancy with associated peritonitis, or a condition which resulted from that.

The operation was performed in January, 1889, and the diagnosis was verified, a three and a half months' fœtus being found. The fluid of the fœtal sac had been absorbed, and lying at the bottom of the sac was found a small and very hard blood-clot. The patient had entirely recovered within five weeks after the operation.

The point which the speaker made was that as soon as a diagnosis of tubal pregnancy had been made an abdominal operation should be performed, as the condition was a constant menace to the patient's life. He was not in favor of using electricity in any form for this condition as he believed it was not a radical measure, and if the fœtus were killed the products of conception would still remain, which not improbably might cause a condition which would necessitate laparotomy. It was better to perform laparotomy before this condition occurred.

DR. W. H. TAYLOR, of Cincinnati, reported a case of

EXTRA-UTERINE PREGNANCY TREATED BY GALVANISM,

in which there were some evidences that rupture had occurred, and it was believed that the diagnosis of tubal pregnancy was clear and distinct. The galvanic current was used with an intensity of one hundred and twenty-five milliampères for a suitable number of times, and the subsequent history was that of complete recovery and well-being of the patient, and gradual diminution in the size of the tumor. It was considered that the electrical treatment had produced a cure in this case.

This paper and that of Dr. Gordon were discussed together.

Dr. JOSEPH PRICE, of Philadelphia, believed that the opinion advanced by Dr. Gordon was correct, namely that tubal pregnancy should be treated by abdominal section as soon as recognized. He did not believe that temporizing with electricity or any other agent was warrantable. Electricians admitted the propriety of laparotomy after rupture had occurred when the conditions had become complicated and the patient's chances of recovery had diminished. Why should they not admit that the same operation should be performed before the unfavorable complications had arisen?

DR. BALDY, of Philadelphia, believed that laparotomy should be done when a diagnosis of tubal pregnancy had been made, and further that it should be done if the diagnosis were not clear and there were only suspicions pointing to ectopic gestation. He failed to be convinced by the statistics of those who had reported series of cases of this character which had been cured by electricity. What had become of the products of conception in such cases? If tubal pregnancy had existed and the fœtus were killed by electricity it would produce the same condition for which laparotomy was now so frequently done, viz., pelvic abscess in some form, hence it was unjustifiable.

DR. E. W. CUSHING, of Boston, approved of the sentiment expressed in Dr. Gordon's paper. He was undecided as to the proper course to pursue in cases in which rupture had taken place, the patient had rallied, but a hematoma appeared to have resulted. It was questionable whether in the uncertainty of such cases laparotomy should always be performed.

DR. A. F. CURRIER, of New York, objected to the implication that men who had had large experience in tubal pregnancy, like Thomas, for example, were unable to make suitable diagnoses. The published statistics of such men certainly did speak in favor of the electrical treatment of tubal pregnancy, especially in view of the success which they believed they had attained by such treatment. It was by no means certain that abscess would follow the death of a fœtus by electricity, as had been implied, and it was not improbable that in many cases the absorption of the products of conception did occur when the fœtus was destroyed prior to the third month, as Thomas had advised. The experiments of Leopold, quoted by Thomas, were in point in this connection, and he believed that all such statements were entitled to a fair and judicial hearing.

Personally, however, the speaker was entirely in accord with Dr. Gordon, and had placed himself on record in the report of a case, published two or three years ago, favoring immediate operation as soon as a diagnosis of ectopic gestation could be made. This might lead to occasional errors, and had done so in three recent cases of which the speaker had knowledge, and this proved the importance and timeliness of the paper on concealed pregnancy which had been read by Dr. Vander Veer.

The speaker was also glad to indorse the plan of immediate operation which had been first advocated by Prof. White, of Buffalo, in behalf of his friend, Dr. Janvrin, of New York, who had earnestly advised this method, and had published an important case in which the inability of electricity to avert a fatal result was painfully apparent.

DR. A. B. CARPENTER, of Cleveland, O., then read a paper on

ALEXANDER'S OPERATION, WITH A NEW METHOD OF SECURING THE ROUND LIGAMENTS.

The question as to the utility of this operation seemed to be settled, but the speaker believed that its greatest utility was in cases of prolapsus. When the operation is done for retroversion he believed that great difficulty might exist in finding the ends of the ligaments, these structures having undergone much traction and consequent thinning. In prolapse he believed the case was otherwise, that the structures involved in the prolapse underwent hypertrophy, and among them the round ligaments. They were, consequently, much easier to find than in cases of backward displacement.

The ligaments having been found, the author's method consisted, after having drawn them out to a sufficient extent and raised the uterus to its normal position, in passing a single silver wire suture through the ligament and the pillars of the ring, as a sort of anchorage suture. The excess of ligament which had been drawn out was then cut off near the ring, and the stump sutured with catgut to the contiguous structures. A drainage-tube was then introduced and the wound closed. Both sides having been thus treated, posterior colporrhaphy should be performed and a Hodge pessary introduced, to be worn by the patient until all the structures are firm under their new conditions. The wire suture which was introduced was intended to be retained permanently.

DR. A. F. CURRIER, of New York, criticised the author's plan of using a permanent silver wire suture by expressing fear that it might, sooner or later, be a source of irritation, perhaps of abscess. Certainly this would be so unless the wire were entirely aseptic, and, in order to be certain as to that point, one must prepare it himself. Wounds made in Alexander's operation seemed to be very prone to suppuration, and, even with very careful operating, the presence of so much fat and cellular tissue was an inviting field for a septic process. He differed with the reader of the paper in believing that the round ligaments could readily be found in prolapse. Of course, experience resulted in skill, and those who, like Kellogg, of Battle Creek, had done the operation many times, were familiar with all the complications and uncertainties which might arise in searching for the ends of the ligaments.

The speaker concurred with the reader of the paper as to the utility of the operation in many cases of prolapsus and backward displacement, and also believed in the simultaneous operation of colporrhaphy and the subsequent use of a pessary.

DR. ELIZA J. C. MINARD, of Brooklyn, presented some clinical statistics in favor of

FREE DISPENSARY AND HOSPITAL WORK.

Aside from the great value of our numerous dispensaries and hospitals as means of charity, we should never lose sight of their value as means of education. Those who were most skilful in surgical and medical work had almost invariably passed years of apprenticeship in dispensaries and hospitals. It might be considered that such long experience in what might to some seem drudgery was the price of skill. In this respect, also, would be apparent the value of the various post-graduate schools which furnished opportunities denied to the average practitioner, especially in early professional life. A word was also spoken in defence of those who performed the so-called mutilating operations upon women. It seemed strange that any defence should be required for the removal of organs which were usually so diseased that their function was abolished, and which, while they remained in the body, were a constant source of pain and distress. The results which have usually followed such operations should speak with sufficient clearness as to their value and the relief which they are wont to bring.

DR. JOSEPH HOFFMAN, of Philadelphia, read a paper on

CRANIOTOMY AND ITS INDICATIONS.

There could be no doubt that there were conditions in which craniotomy was an operation which should be performed. It was extremely desirable to know what place it should occupy in view of its merits or its faults. If the long list of indications which some writers have given is to be taken seriously, then Tyler Smith's plea for the abolition of the operation is worthy of consideration. These alleged indications certainly showed to what an extent the operation had been abused. The object of craniotomy must be considered to be the saving of the mother's life, especially in cases in which the fœtus is already dead.

The general indications for the operation should be fœtal deformity, including hydrocephalus, monstrosity, or any serious deformity which can be appreciated as an obstruction to labor, and pelvic deformity of varying degrees, not including those cases in which the conjugate diameter was two inches or less. As to the morality or immorality of the operation, in the abstract, the accoucheur could not deal with that question. The purpose of the operation was conservative—to save the mother's life by sacrificing the child's, if necessary, one life being lost instead of two.

For those cases in which the conjugate diameter was two inches or less, the Cæsarean section had long ago been advocated by Hodge and others, when that operation offered far fewer chances of success than it now does, the direction being given then as now that it be performed early. The speaker could not agree with those who advocated early hysterectomy, as did Tait, or Cæsarean section, on the ground that they were simple operations. For any operation of this character skill was required. As an argument in favor of craniotomy it must also be admitted that many infants which are born after protracted labors, perhaps after instrumental delivery, are born dead, and that many others, even if born alive, have been so injured in the process of parturition that they survive but a few hours or days.

DR. LOVEJOY, of Haverhill, Mass., was in full accord with the reader of the paper. In an experience of more than three thousand labors during forty years among people who were largely of Irish nativity, he had found it necessary to perform craniotomy on a number of occasions. He believed it to be not more difficult than forceps operations, and not so dangerous as version. The indications with him had been contracted pelvis, prolonged labor, etc. In none of his cases had there been a maternal death.

DR. A. F. CURRIER, of New York, objected to the idea that craniotomy could be considered in any sense a

simple operation. There was not merely the destruction of the child and its extraction to be considered, but there were the soft parts of the mother as well. He had seen serious injuries to these at the hands of one of the most skilful operators in the Vienna Maternity Hospital. In his own experience he had found the operation extremely difficult, and it was one of the operations which one did not care to do very often.

DR. WILLIAM H. PARISH, of Philadelphia, had never done the operation upon a living child. It was warrantable to perform it if the child were dead and the mother's powers were failing. With the advantages and the comparative safety of the Cæsarean section at the present time craniotomy should be less frequently performed. The operation was a cruel one, and, as usually performed, unjustifiable. It was not enough that the father and mother consented to the destruction of the child. They had no right to give away the child's life, and the child had rights which should be respected. As a rule, he would say that craniotomy upon a living child was not justifiable.

DR. HENRY D. FRY, of Washington, D. C., agreed with the previous speaker that the operation should be done as infrequently as possible, and was also of the opinion that it was done when it should not be.

DR. WILLIAM H. WATHEN, of Louisville, spoke with great earnestness and feeling respecting those who found occasion to do this operation frequently. So abundant are the resources of modern obstetrics, so great the success of careful and conservative obstetricians, that it should not be allowable for the opinion to go forth that the Section regarded with any favor the frequent performance of this destructive operation. He quite agreed with a previous speaker that it should not be done upon a living child.

DR. E. F. WALKER, of Providence, R. I., reported a case of a

DOUBLE-HEADED MONSTER.

This most rare and beautiful specimen of ischiopagus was exhibited in an excellent state of preservation. The author had been able to obtain but a meagre history of the labor in which the specimen was born. The mother was attended by an ignorant Irish midwife, and the details which she had given were unsatisfactory. The midwife would not reveal the name of the mother, so that she could not be interviewed. The mother was a married Irishwoman, thirty years of age and a primipara. Her labor began in the afternoon of July 15, 1888; the midwife ruptured the sac at 1 A. M. the following morning, and the pains continued with additional severity until 5 A. M., when the entire fœtal mass came away, the placenta following after an interval of five minutes. There was little hemorrhage and the midwife was unable to say whether there had been much injury to the soft parts. The patient recovered rapidly, was doing her work again within a week, and was now pregnant again. The monster lived twenty-six hours, cried at birth, and took milk freely by both mouths. Its weight was about fifteen pounds. There was one placenta, one cord, no history of fright, injury, or anything else that was unusual during pregnancy, as far as could be ascertained.

The mass was crescentic in shape, its longest surface following the line of the abdomen, and measuring twenty-one inches from vertex to vertex. It consisted of two bodies joined together at the buttocks, with a head at each end. The larger body has a trunk, two arms, two legs, and is well developed. The smaller one has the right arm and leg well developed, the left forearm and hand are deformed, the left foot and leg are also deformed. The left hand has but three fingers, which are of unusual length; the left foot has a short little toe, caused by absorption of the metatarsal bone; the third and fourth toes are webbed. At the umbilicus of the larger child is a placental-shaped mass, 3½ x 4½, convex outwardly, to which is attached a cord which went to a normal placenta. The umbilical mass is firm and lobulated.

The smaller child has a protuberance springing from the back of the neck, which is suggestive of spina bifida. It is soft, apparently contains fluid, and measures 4 x 3. The larger child has, apparently, an imperforate anus. Between the left thigh of the larger and the right thigh of the smaller is the vulva, having an undeveloped labium majus upon the right side.

SECTION OF THE DISEASES OF CHILDREN.

J. A. LARRABEE, M.D., of Louisville, Ky., Chairman.

TUESDAY, JUNE 25TH.

THE CHAIRMAN, DR. J. A. LARRABEE, read a short

INTRODUCTORY ADDRESS,

referring in eloquent terms to the labors of the members of the Section and to the historic associations of the place of meeting. Pediatrics, he said, is not a forced specialty, torn from the tree of medicine. The diseases of infancy and childhood have something in common with the diseases of adult life—nomenclature—but differ so widely in course, duration, and consequences as to be fitly the subject of especial study. Still, as in Addison's vision of the bridge of life, the pitfalls are thickest at the entrance, and much that would assist to reduce infant mortality might be learned through the labors of a committee on vital statistics of infancy, to be appointed each year and to report at a stated time.

He also referred to the subject of infants' foods, and to assertions made by certain manufacturers tending to throw discredit upon the Section, and advised the passage of a law prohibiting the publication by manufacturers of expressions of opinion made in the Section.

On motion, a vote of thanks was extended to the Chairman, and a Committee, consisting of Drs. Love, Brush, and Watson, with the Chairman, was appointed to consider and report upon the recommendations contained in the address.

DR. T. B. GREENLEY, of West Point, Ky., then read a paper on

THE MANAGEMENT OF INFANTS DURING THE FIRST YEAR.

Improper food, neglect, unsanitary surroundings, and infanticide are, he said, the great causes of infant mortality. Syphilis kills a large majority of those dying in the first two months of life. Licensing and inspection of prostitutes would diminish this disease. Among the recommendations made, were the wearing of caps and bandages, and, when artificial feeding is necessary, the use of cow's milk undiluted, in order that the stomach should not be unduly distended by the excessive amount needed if diluted.

DR. SEARS, of Texas, had no doubt that proper food, clothing, and ventilation would diminish early mortality. He agreed with the reader that the commencement of life was all important. Some children starve in the midst of plenty through ignorance on the part of mothers as to the time, quantity, and manner of feeding. He thought flannels should be worn until the seventh year of age.

DR. WILLIAM PERRY WATSON, of Jersey City, objected to the wearing of caps by infants. Keep the head cool and the extremities warm. There is no reason why an infant should have a simple tonsillitis or laryngitis, any more than a simple nasal catarrh; but we know very well that, except in syphilitic cases, we do not have snuffles. If head and neck are left uncovered, children grow up less liable to croup and sore throat, etc.

DR. CHRISTOPHER, of Cincinnati, thought it incorrect to say "no snuffles without syphilis."

DR. WATSON qualified his remark by saying that if the head is left uncovered, very few non-syphilitic infants have nasal troubles.

DR. CHRISTOPHER referred to the advice of the reader of the paper to take sick children to the country. All were familiar with the improvement that change of air wrought, especially in weak and bottle-fed children. Bowel troubles, prone to recur, disappear on change of location. In institutions we are careful to disinfect stools, etc., but in private homes we are not likely to think it necessary. Is there not an infected atmosphere here, too, from which, when removed, the child naturally recovers?

DR. BRUSH, of Mt. Vernon, N. Y., thought it unnecessary to feed milk to infants during the first two or three days. Very few mothers have milk until the third day. He objected to the recommendation of milk and lime-water in cholera infantum. In cities the first thing is to stop milk at once.

DR. LATIMER, of Baltimore, thought that where the infant starts free from disease and parents are healthy, the child should be put to the breast within a few hours and continue at stated intervals. As a substitute for mother's milk, cow's milk is the most available. He preferred Meigs's method of preparation, after which it should be sterilized. The quantity must be determined by observation, as children differ greatly. To nurse infants more than once or twice during the night is injurious both to the mother and the child.

DR. FARRINGTON, of New York, does not feed the newborn infant—the child cries not from hunger. It is well to put it to the breast every two hours, to establish good habits.

DR. GREENLEY said that his recommendation as to caps was meant only to apply to the winter season; especially in the district in which he practised was it necessary. His recommendation of milk and lime-water in cholera infantum was as a medicine to allay nausea, not as a food. He excludes all food during the acute symptoms.

SECOND DAY—WEDNESDAY, JUNE 26TH.

DR. PETER HOOPER, of Philadelphia, read a paper on

THE INTESTINAL DISEASES OF CHILDREN DURING HOT WEATHER.

He advocated the abstraction of heat from the patient by cool bathing, cold drinks, cracked ice in the mouth, ice bags to head, spine, and abdomen. Lumps of ice should be placed in the room to cool the air. Enemata of tepid or medicated water to wash out the colon were advised in cases attended by offensive discharges. In cholera infantum there should be absolute rest and abstinence from food for twenty-four hours. The best treatment is prophylaxis. Cow's milk is the best artificial food, and in some cases undiluted. Plenty of cool, fresh air with moderate sunshine, but without exposure to direct rays of sun. Flannels should be worn the year round, and an abdominal bandage day and night. The child should be bathed every night and every morning.

Probably the heroic treatment of the future will be to open the bowel and wash it out.

Inunctions of warm oil soothe and nourish, allay restlessness and diminish fever. Pepsin used in intestinal diseases should be soluble and free from inspissated mucus.

DR. S. SOLIS-COHEN, of Philadelphia, commended the use of cold water and ice, internally and externally, as advised in the paper, rather than chemical antipyretics, which are usually depressing agents, in cases where reduction of temperature is indicated.

DR. LARRABEE believed it to be important to distinguish between the various diseases under discussion. Are they all of the same etiology and do they admit of the same treatment? In cases due to heat, thermal diarrhœa, there is no agent equal to cold. He differed from Dr. Hooper in his understanding of the term cholera infantum. Cholera infantum does not have green, slimy, lumpy stools. It is probably caused by a ptomaine, and it is the analogue of cholera in the adult. Suddenly the child is seized with purging and vomiting. There are profuse watery discharges. There is a serous exosmosis, and, in young infants, the fontanelle sinks and the expression is changed. The child becomes pinched, blue, and cold. It lingers, sinks, and finally dies.

Cases of this kind must be differentiated from thermal diarrhœa. The treatment must be applied instantly. We cannot wait to get rid of the ptomaine, or to make the bowel aseptic. For ten years or more he had treated such cases by immediate hypodermatic injection of morphine and atropine. About $\frac{1}{200}$th gr. of the former, and a very minute dose of the latter. He dissolved in an ounce of water a pellet consisting of $\frac{1}{4}$ gr. of morphine and $\frac{1}{60}$th gr. of atropine, and used about ten drops in a child a year old. The treatment had been thoroughly successful. It changed the osmosis. To correct the local conditions no drug excels calomel. We use it as an antiseptic, our fathers used it to move the liver. The explanations differ, but the result is the same. He objected to bandages. In entero-colitis evacuation is the proper treatment, but he preferred salines to relieve the strangulation of the vessels, according to the best surgical practice in peritonitis. Inunction of oil does more than simply lubricate and protect, it is a stimulant to the peripheral nerves.

DR. I. N. LOVE, of St. Louis, said that diseases of infancy are due to interference with and interruption of nutrition. The first month is the most important. Next to a wet nurse for an infant deprived of its mother's breast is a good healthy cow, or goat. The milk should be sterilized according to the plan of Rotch, by steaming in bottles to 180° F., and then tightly closing the bottles.

But in some cases artificial food must be used, because milk cannot be digested however prepared. Mellin's and Carnrick's foods had given him satisfaction, as had Bovinine in some cases. If feeding is properly accomplished, we would not have to discuss treatment of intestinal diseases. Mercurial treatment is the best. Cool baths should be given at proper intervals, and cool sterilized water to relieve thirst and prevent over-feeding. He advocated the flannel bandage, and confirmed Dr. Larrabee's reports of the good effect of morphine and atropine hypodermatically in cholera infantum.

DR. W. PERRY WATSON referred to the practice of exposing the legs of children for fashion's sake as productive of disease. He keeps the extremities and the abdomen covered, the head cool. In many cases milk, no matter how prepared, cannot be retained. He stops it and uses a remedy which he learned from Dr. Brush, oatmeal water with a little salt and sugar. It is given cool, in small quantities and at frequent but regular stated intervals. In the meantime, if the child cries, a teaspoonful of hot water may be given as often as necessary. Cholera infantum usually follows other diseases, but may occur suddenly. It usually comes on the third or fourth of a series of hot days. The best treatment is preventive.

DR. BRUSH said that by visiting cow pastures one could predict the occurrence of epidemics of cholera infantum in the cities. There are certain weeds cows avoid in cool weather when grass is plenty—lobelia, buttercup, poison ivy, etc. Little clumps are left on the field. But after two or three days of hot weather these clumps disappear, the poisons taken in by the cow are excreted in her milk, and that is one cause of cholera infantum in bottle-fed babies. The treatment is to stop the milk and give chloroform in emulsion with castor oil and gum arabic. It is a stimulant to prevent collapse, a disinfectant and an analgesic. He differed with Dr. Love as to the use of commercial foods. Some of these are largely made with waste products of various industries, as the refuse roe from salmon canneries, whey from cheese factories, etc. One, which had been mentioned, was largely made up of the blood from slaughter houses, whiskey being the preservative.

Now, with such a food we cannot tell whether the animals, from which it came, were healthy or diseased. But if we get meat we can examine it for ourselves, and then make a beef preparation in such a way as we may prefer. We should always be able to prepare, in the patient's house, whatever food is needed, from milk, or from cereals, or starches, or meat.

DR. MEYER, of New York, referred to the confusion of terms, looking upon cholera infantum as a very rare disease. Morphine with atropine was the remedy. He had never found occasion for the use of commercial, artificial foods.

DR. LOVE said he would use commercial foods like drugs with great discretion, and never when other means were available and equally efficacious. They were tools, and he could not always stop to manufacture his tools. If he found a good tool in the shops it was better to buy it and use it properly. Again, we must take homes as we find them. We could not trust home manufactures in every instance. Manufacturers of infant's food were men, and he would be sorry to learn that human nature was so base as to put filthy refuse products on the market for so sacred a purpose as the feeding of infants. No terms were too severe to condemn such action, but he did not believe that all manufacturers were morally torpid.

The Committee on Nominations reported the following nominations for

OFFICERS FOR THE ENSUING YEAR.

President, I. N. Love, of St. Louis,
Secretary, E. F. Brush, of Mt. Vernon, N. Y.,
and they were unanimously elected.

DR. F. E. WAXHAM, of Chicago, forwarded a paper entitled

INTUBATION OF THE LARYNX WITH REPORT OF CASES,

which was read by the Chairman.

Dr. Waxham reported 60 additional cases with 28 recoveries, or 46.66 per cent., which, with cases previously reported, made his record to date 210 cases with 79 recoveries, 32.89 per cent. The cause of the greater success latterly was not unnecessary operation; on the contrary, nine-tenths were done as a last resort, some of the children being moribund. As to medicinal treatment, of 19 cases that had corrosive sublimate before and after intubation, 9 recovered, 47.36 per cent; of 28 cases treated with the same drug only after operation, 14 recovered or 50 per cent., while of 13 cases that had not been given the drug at all, 5 recovered, or 38.46 per cent. The type of disease was not different. The improvement in the method of feeding, namely, having the child drink in the inclined position with the head down was the greatest factor in the increased success. The artificial epiglottis was now unnecessary. Another element was a more watchful care. A frequent cause of death had been detachment of membrane beneath the tube, choking the windpipe. By using a tube with less swelling it was more easily expelled and the membrane would also be coughed out. Large tubes fitting tightly, therefore, are dangerous. No danger was to be apprehended from expulsion of the tube, if the operator or a competent substitute could be summoned quickly to replace it. Partial detachment of membrane would be indicated by hoarse cough, when the tube should be at once removed. The membrane would then be expelled. The operations were all but one for membranous laryngitis. An exceptional case was one of laryngeal stenosis with measles. The patient died.

Age.	Number of Cases.	Number of Recoveries.	Percentage of Recoveries.
Under 2 years	11	3	27.27
Between 2 and 3 years	8	2	25.
" 3 " 4 "	9	4	44.44
" 4 " 5 "	17	8	47.05
" 5 " 6 "	4	3	75.
" 6 " 7 "	3	3	100.
" 7 " 8 "	5	4	80.
" 8 " 9 "	2	1	50.
12 years	1	0	0.
	60	28	46.66

The youngest patient was six months; it died. The cases of recovery under two years were aged fifteen, eighteen, and eighteen months respectively.

DR. GAY, of Boston, said that at the Boston City Hospital the statistics were slightly in favor of the older operation, but the new prevails as being, on the whole,

easier to do. In some cases none have been able to get the tube into the larynx. It requires as much help, as there is as much danger of the patient dying under the hand of the operator as in tracheotomy. 10 cases in 310 of tracheotomy had died from ether, shock, prostration, or hemorrhage. In intubation an equal number of deaths occurred from strangulation and shock. Even if deposited with the utmost care, there was a moment of strangulation with every intubation. If it did not immediately pass off, the tube should be removed and the membrane will be coughed out. By persistently trying to force in a tube which always causes a strangulation life might be lost. When the stenosis was not relieved by the tube, or swallowing was impossible, or the tube constantly coughed up, tracheotomy was indicated in the majority of cases. In 32 cases in which intubation failed and tracheotomy was then done, 3 recovered. The type of disease influenced the result very much. There was no fixed treatment aside from operation. He had used bichloride faithfully for two years. At one time he thought more recovered, but now he said that the facts do not warrant any conclusion. Feeding is very important. In intubation it should be done with the child lying down, and on one side. There was no pathological evidence that the inspiration of food causes death. All know how the tracheal tube became jammed up. The intubation tube did not. It became blocked below but not lined with membrane.

Outside the hospital Dr. Gay did intubation among poor people who could not properly care for the tracheotomy tube. He saw the child as often as he could. A certain number were and would always be lost from inability to find the operator at the time of blocking of the tube or when it was coughed out. On the whole, intubation was the better operation in ordinary cases.

DR. DENNISON, of Colorado, thought it needful to inquire into the effect of annihilation of the function of the larynx in intubation as well as in tracheotomy. Pulmonary complications caused seventy per cent. of the deaths. He had performed intubation twenty-five times with seven recoveries. Nine of the eighteen deaths were due to œdema of the air cells from aspiration of the blood toward the lungs while breathing was suspended. In Colorado they had to breathe five times more in the minute to get sufficient oxygen on account of the lower air pressure (twelve pounds instead of fifteen pounds, as at sea level) and this affected little children remarkably. In his fourteenth case he noticed that the pulse was weak during inspiration and strong during expiration. The blood could not get out of the thorax while the latter was distended with entrance of air impeded. He operated and recovery ensued. Where aspiration of blood has already occurred before operation recovery is almost impossible. Death ensues from œdema in twelve to thirty-six hours; average twenty-six hours. We need to study this question to get the best results from the operation.

DR. BRUSH said that he had found Dr. O'Dwyer modestly at work in the hospital, had asked and obtained permission to publish the results, and had gone enthusiastically into the practice of intubation. His record was twenty-three operations with one recovery, the latter the only one in his own practice. Recently he had intubated an adult, who was relieved but died twelve hours later. It was a mistake to persevere in attempts to put the tube in, when there was great difficulty. It was necessary for the operator to examine the case and refuse to intubate when there was pulmonary œdema, for in such cases no relief is afforded and the operation lost prestige. Even when children died, the parents admitted the relief, and were willing to commend the operation for that reason. He doubted the entrance of food into the lungs. It was the ineffectual cough which set up the irritation, causing pneumonia when there was not an extension of the disease in the throat.

DR. LARRABEE had had experience with tracheotomy only, with twenty-five per cent. of recoveries. No two subjects admitted of such equal balance of opinion. If the dangers of tracheotomy were a Scylla, those of intubation were a Charybdis. It was said that intubation was less difficult. This arose from personal experience. Certain men possessed or acquired a technical facility, like Tait in laparotomy or Waxham in intubation; but others could not attain the same brilliant results. To him intubation was far the more difficult operation. It was more popular with families because it was bloodless. Operations were reported indiscriminately whether for croup or diphtheria. But a distinction should be made. Membranous croup is a local disease—an exudation without sepsis. Diphtheria is a systemic infection. In croup we operate and cure; in diphtheria we relieve but one symptom and have the disease still to fight. Tracheotomy gives the better prospect because it interferes less with alimentation. It did not require cessation of medical treatment, of the iron, internally, externally, eternally, on which he depended, with food and whiskey, for the cure. The pressure of the membrane still left below the tube is unfavorable. For infants under two years, and in croup, intubation held first place; but tracheotomy in older children with diphtheria. As to the blocking of the tracheal tube by covering it with a sponge moistened with hot water, or by proper arrangement to keep up steaming, this could be avoided. Too much importance was attached to pneumonia. He was in the habit of medicating through the trachea, pouring down a drachm of a solution containing chlorinated soda, and found the cough it excited beneficial in causing expulsion of membrane.

The condition alluded to by Dr. Dennison was present, but not due to either intubation or tracheotomy. It was found when no operation had been performed. Tracheotomists were familiar with the venous turgescence caused by the non-return of venous blood, and how often timid operators had suffered the child to die by trying to arrest hemorrhage from such distended veins, when by opening the trachea the condition could be at once relieved.

DR. HENRY D. CHAPIN, of New York, then read a paper on

PSEUDO-MEMBRANOUS RHINITIS.

Can there be a croupous inflammation of the nasal mucous membrane entirely apart from a manifestation of diphtheria he asked. Schwalbe, in 1871, reported the case of a boy, five weeks old; and Hartmann, in 1887, reported six cases in children from three to seven years, in which casts of the nasal passages were expelled or removed, consisting of pseudo-membrane microscopically indistinguishable from diphtheria. Other reported cases were alluded to, which occurred both in children and adults, and two original cases were added to the list.

Dr. Chapin's patients were sisters, aged two and three years respectively. The latter was first attacked, and presented the most marked manifestations. Two weeks before coming under observation, a discharge from the nose began, and was accompanied by coughing and sneezing. General condition was good. There was no fever. The nose was packed with fibrous material, the throat only congested. For the next few days shreds of membrane were thrown off from the nose, and on several occasions large masses were detached with forceps. Bleeding followed. Temperature was but slightly elevated. There was so little disturbance, except from nasal stenosis, that the parents would not confine the children to bed, and they played around as usual. The urine was never albuminous. In view of the entire absence of sepsis while the nose was packed with membrane, which, if infectious, would soon have poisoned the whole system, the author concluded that the disease was not diphtheria, notwithstanding that the microscopic examination showed no difference between the pseudo-membrane and that of diphtheria.

DR. S. SOLIS-COHEN, of Philadelphia, referred to the great variety of forms of pseudo-membranous inflammation of the air-passages, and to pseudo-membranous enteritis, and thought the peculiar response of mucous membranes to different sources of irritation sufficient to explain Dr. Chapin's and other cases, without any necessity for calling in the aid of a specific poison.

DR. COCHRAN, of Massachusetts, reported cases of extension of diphtheritic casts of the nasal chambers. Diphtheria might be localized in the nose, or extend to the throat, and death or recovery might take place in either case.

DR. LARRABEE thought the matter of identity of all pseudo-membranous inflammations could not be settled by mere microscopic identity of the product. The clinical history was equally important, and herein great differences existed. Any irritation might produce it, or a specific poison might give rise to local and general infection. In the one case the patient got well with removal of the membrane, in the other it continued to form again and again, even on scratches of the body. Croup was not epidemic, it came with the vicissitudes of weather and changes of temperature. Diphtheria comes as infection, and spreads from child to child, and from house to house.

DR. CHAPIN said that Dr. Cochran's cases were quite different from his. Nasal diphtheria was an infectious disease, and when matter filled the nose without causing infection, we could argue that it was not of an infectious nature.

DR. C. R. EARLEY, of Pennsylvania, read a paper on

SCARLATINA.

He doubted its contagious character, and urged sanitary precautions as prophylactic means. He denied its identity with diphtheria, and referred *in extenso* to the various sequelæ and their treatment, it being important to recognize the cause. The treatment of cases of scarlet fever varied with the locality and the season. In mild cases very little interference was needed. He gave ipecac as an emetic, with caution, and administered cooling drinks freely. In the anginose form he used chlorate of potash, oil of turpentine, quinine, carbonate of ammonium, with free use of cold water and ice to the throat. As a gargle, chlorate of potassium, capsicum, and chloride of sodium, or sulphate of zinc, creasote, and myrrh; or chlorate of potassium, chloride of sodium, bichloride of sodium, and gum acacia. To prevent gangrene he used ergotine with camphor, iodine, and glycerine. Several cases were given in support of the various propositions advanced.

THIRD DAY—THURSDAY, JUNE 27TH.

DR. S. P. DEAFHAFE, of Potsdam, O., read a paper on

POLIOMYELITIS ANTERIOR ACUTA.

He had seen five cases. He considered it an acute inflammatory affection of unknown origin. Cold and dentition are doubtful causes. Nothing indubitable is known of a specific microbe. We cannot trace heredity. Onset with fever may be abrupt. One lower extremity is most frequently affected, the temperature of the part becoming subnormal. Diagnosis and treatment were discussed at length.

DR. KING, of Chicago, had seen three cases in adults, in whom it was possible to obtain symptoms not seen in children. The bladder was always paralyzed, but recovery was prompt. Tactile sensation was unaltered. In early stages electrical treatment did harm. When but one extremity was affected the lesion was upon the opposite side of the cord, yet the knee-jerk of the apparently sound side would be absent.

THE CHAIRMAN spoke of the difficulties in diagnosis, especially with regard to rheumatism. He had formed a low estimate of the therapeutic value of electricity.

DR. I. N. LOVE, of St. Louis, read a paper on

ONE YEAR OF ACETANILIDE IN PÆDIATRIC PRACTICE.

He considered acetanilide superior to all of the carbolic acid series. He believed it better to use the name given in the title in preference to that of "antifebrin." He considered it three times more effective than antipyrin and less depressing. If it does diminish the red blood-cells, it does so slowly after long administration. Depressing effects came from poor makes of the drug. He agreed with Widowitz in his view of its safe and steady action with children. He did not believe that the disagreeable cyanosis was of especial importance, and it could be obviated by combining with alcohol. He made mention of the use of the drug in scarlet fever, measles, and congestive fevers. The author spoke of the treatment of fifty cases of whooping-cough, and thought it a valuable remedy. He also mentioned its use in convulsions and chorea. In conclusion, the writer stated that acetanilide, carefully guarded and properly used, is a safe and reliable remedy in the diseases of infancy and childhood. It is preferable to antipyrin, because it does not cause so much depression and its effects last longer. The cyanosis is not dangerous, though it is a disagreeable feature. It is of value in controlling temperature in various fevers caused by the typhoid germ, malaria, or the exanthemata. It serves almost as a specific in whooping-cough by mitigating the discomforts and controlling paroxysms. He was opposed to the sale of these carbolic drugs over the counter.

DR. DIXON, of Kentucky, had given it, followed by quinine, in malarial fevers. In whooping-cough he preferred antipyrin.

DR. HILL, of New Hampshire, had seen good effects from acetanilide in asthma.

DR. KING, of Chicago, related a case of cerebral tumor, in which large doses had been given—twenty grains at one time—for relief of pain.

DR. WATSON, of Jersey City, thought it better not to do anything in self-limited fevers.

DR. ATKINSON, of Baltimore, had not seen the impure drug. He did not think it could modify the fever process, though it could contribute to the comfort of the patient.

DR. OSLER, of Baltimore, had given acetanilide in the cold stage of fever, but he believed that it was useless.

DR. LOVE, in closing, said that cyanosis was best treated by giving alcohol at the same time with the drug.

AMERICAN NEUROLOGICAL ASSOCIATION.

Fifteenth Annual Meeting, held at Long Branch, N. J., June 26 and 27, 1889.

JUNE 26TH.—MORNING SESSION.

THE PRESIDENT, E. C. SEGUIN, M.D., called the Association to order.

DR. MORTON PRINCE, of Boston, presented a paper on

MALARIA AS A CAUSE OF DEGENERATIVE DISEASE OF THE SPINAL CORD.

He spoke of the frequency of tabes and other spinal degenerations in cases which also presented a history of malaria. The first case he had recorded was one of locomotor ataxia with typical tabetic crises before each malarial chill. Another had gastric crisis regularly once monthly, and another crisis beginning with rigor and followed by diarrhœa, this occurring every three weeks. The latter case had been diagnosticated as malaria by the family physician. Altogether the author reported in detail six cases, showing the coexistence of tabes with malaria; and six cases in which the malarial history was associated with disseminated sclerosis. Besides these he had notes of three other cases of multiple sclerosis, two of locomotor ataxia, and one of lateral sclerosis with a similar relation. Generally the malarial poison was present in the system previous to the development of spinal symptoms. He pointed out coincidences in the course of syphilis and malaria, such as the slowness of action of the poison and amenability to treatment; and also called attention to the relation of the syphilitic virus to tabes. He had found but little to support his etiological theory in literature. Erb, following Schulze, had stated that tabes may occur as a sequel to intermittent fever. Tuczek had proven that tabes could be caused by the ergot parasite. Many nervous disorders are undoubtedly due to malaria, such as neuralgias, anæsthesias, severe psychoses, etc. He alluded to the deposition of pigment in the brain in some cases of pernicious malaria. It would be very important for many army pensioners if it could be definitely determined that tabes and sclerosis might be sequelæ of malaria.

DR. N. F. BRILL said that his attention had never before been directed to the possibility of such a relation, but he thought the details presented were rather too meagre for an absolutely correct decision to be made in the matter. As neuritis and malaria were frequently associated, possibly some of these spinal cases might be coincident in the same manner. Both malarial and cord disorders are very common.

DR. L. C. GRAY saw no reason why the malarial poison should not cause spinal diseases. We do not yet know the exact character of the poison. But there is a sort of periodicity in many spinal and cerebral disorders, as well as in peripheral nervous affections, which is often as marked as that of fever and ague. He had noticed this particularly in intracranial syphilis. Some of these neuropathies were even relieved by quinine, as he had observed in cases of tabes. When we speak of latent malaria and rest our diagnosis merely upon periodicity, there is danger of error. If Laveran and Councilman were right in their discovery of the malarial germ, this should be looked for in such cases as the author had described, in order to corroborate with certainty the diagnosis. Improvement or recovery under the use of quinine was no criterion.

DR. E. C. SPITZKA saw nothing in the nature of the case to forbid an etiological association between malaria and cord disorders, but he agreed with the preceding speakers that sufficient proof of such relation had not been adduced. To show an etiological significance, it was necessary to present absolute and intrinsic proof of it. If it could be shown that, as in syphilis, there were at the time of the malarial attack nervous symptoms, it would be a different matter. In the secondary fever of syphilis there was absence of the knee-jerk. Most nervous symptoms in malaria were of a neuralgic character. The anæsthesias differ from those of tabes. It had been found that pigmentary thrombosis or embolism were the most frequent causes of serious nervous disturbances in malaria. He believed, however, that, like any other cachexia, antecedent malaria might predispose to spinal affections. He had observed a case of paretic dementia of the tabetic type which was probably influenced etiologically by severe malaria.

DR. H. M. LYMAN, of Chicago, could recall but two cases where it had been intimated to him that the origin of tabes had been malarial. In one he traced the actual cause to a subacute spinal meningitis coming on after exposure to wet and cold. The other case instead of being true tabes had proved to be a rheumatic neuritis. He had in his experience seen nothing to support the idea of a malarial etiology in tabes. A complete and perfect history together with a microscopical examination of the blood should be required for an indisputable diagnosis of malaria.

THE PRESIDENT could not recall a single case of tabes or multiple sclerosis which presented any relation to malaria.

DR. PRINCE thought there could be no question as to the correctness of diagnosis as regarded the nervous symptoms in his cases, and as to the antecedent malaria; all of his cases were men who had been in army service, and he had documentary proof of their having suffered from that poison in the shape of government records. The really doubtful question was whether the malarial poison still existed in the system at the time of the development of the spinal disorders. In some of them there was evidence of its persistence in the shape of typical malarial rigor and pyrexia. He did not consider his etiological explanation decisive, but merely suggestive.

DR. SPITZKA thought that there were many cases of nervous disease owing their origin to exposure during the

war which were contemptuously rejected by the Pension Bureau. It seemed to him that the Association ought to call the attention of the government to the great injustice that might be done.

THE PRESIDENT, although once an army surgeon, and, therefore, prejudiced in favor of the soldiers, had been on the contrary struck by the vast number of fraudulent nervous cases which were awarded pensions.

ELECTIONS AND RESIGNATIONS.

Drs. W. M. Leszynski, of New York, C. Eugene Riggs, of St. Paul, N. S. Upson, of Cleveland, H. A. Hare, and J. P. C. Griffith, of Philadelphia, were then elected to active membership; and Mr. Victor Horsley and Dr. David Ferrier, of London, were elected to honorary membership. The resignation of Dr. A. D. Rockwell, of New York, was accepted.

AFTERNOON SESSION.

DR. B. SACHS, of New York, reported a case of

NUCLEAR OPHTHALMOPLEGIA WITH POLIOMYELITIS (POLIOENCEPHALITIS SUPERIOR AND POLIOMYELITIS).

The relation between these two forms of disease which had been suspected by Hutchinson, Mauthner, and others was proven by this case. But one other was on record, that of Seeligmuller. The history of the patient was briefly that a ptosis of the right eye gradually developed, followed after a few months by ptosis of the left eye also, and soon after a paresis of all the external ocular muscles of both eyes appeared. This resulted in almost absolute fixation of the right eye, but left a slight inward and upward movement of the left. There was immobility of the left pupil to light, but not to accommodation. The right could not be examined because of corneal opacity. During the development of this nuclear ophthalmoplegia, a subacute poliomyelitis affecting the entire right leg supervened. There was now marked atrophy of the entire right leg. The knee-jerk was lost on both sides. There were no sensory disturbances. There were no tabetic symptoms, and the patient's condition was normal in all other respects. This case proved that the affection of the nuclei in the floor of the third and fourth ventricles was due to the same pathological process which gives rise to poliomyelitis when it affects the gray matter of the cord.

DR. SPITZKA said the report of the case had been so complete and there being but one other such case on record, it did not admit of either criticism or comparison. He referred to Thomsen's case of unilateral nuclear paralysis, where there was a gummatous infiltration on both sides, and the explanation of which was to him quite impossible.

DR. SACHS asked if fibres could be traced up through the ciliary nuclei.

DR. SPITZKA answered in the affirmative and made blackboard drawings illustrative of their course.

DR. J. J. PUTNAM, of Boston, then presented, through Dr. W. N. Bullard, a skull which was a remarkable example of

HYPEROSTOSIS CRANII.

The case had been reported to the Association two years ago. The patient was a woman, thirty-one years old at death. The chief symptoms were headache, broadening of the head, dropping out of the teeth, loss of hearing, vertigo, beginning gradually some years ago. There was extreme exophthalmos. There were no retinal changes. Extensive pachymeningitis was discovered at the autopsy. There was thinning and atrophy in parts of the skull. The orbital cavities were greatly diminished in size. Virchow considered hyperostosis cranii due to inflammatory changes. In this case probably the inflammation originated at the ear. Dr. Putnam had a patient now with similar symptoms, in whom the exostoses were first noticed in boyhood, and he desired the opinion of members as to the justifiability of removal of certain exostoses for the relief of pain. Dr. Bullard himself thought it might be difficult to determine which of the exostoses produced the pain. Some of the exostoses were very diffuse and the operation might have to be extensive.

THE PRESIDENT believed that the pain would be more apt to originate from basal lesions, possibly dural inflammation about the issuing nerves. The jaw in this case was interesting because of its senile conformation and angle, despite the youth of the patient.

DR. W. M. LESZYNSKY, of New York, read a paper entitled

SPONTANEOUS DEGENERATIVE NEURITIS OF THE BRACHIAL PLEXUS.

The patient was a laborer, aged thirty-eight. He first had pain in the left shoulder, shooting down the arm, which was ascribed to exposure to wet. There was then no involvement of the shoulder-joint and the motility of the arm was unimpaired. All the muscles reacted well to faradism, except the deltoid, which was atrophied. There was no sensory disturbance, but there was pain on pressure. Gradually other muscles became paralyzed, until a large number of the arm muscles were useless. The paralysis was accompanied by pain so excruciating that the patient could not sleep at night. A feeling of numbness extended from the shoulder down the arm over the radial distribution, and a gradual anæsthesia and analgesia supervened throughout the same area. The faradic excitability disappeared, and there was galvanic hyper-excitability. Then he began gradually to improve, and will ultimately recover. The case was remarkable in its severity, in its idiopathic origin, and in the escape of the median and ulnar nerves from the inflammatory process. Not more than one case had to his knowledge been found in literature.

DR. PRINCE thought it would be difficult in the early stages of such a case to distinguish it from progressive muscular atrophy of the shoulder type. He recalled a case of his own in which there was every reason for considering it to be neuritis. It began with cramps such as are observed in writer's cramp, and it was several years before other symptoms proved the case to be one of progressive muscular atrophy. The most common cause in such cases as the author's was traumatic arthritis, but generally the results are slight.

DR. W. R. BIRDSALL had seen this case before, and was impressed with the idea that it might be a periarthritic affection, but the author's careful study of the case seemed to exclude this. He recollected that at that time there was some ankylosis of the shoulder-joint in the case.

THE PRESIDENT considered the study of the differing

resistances in the healthy and diseased arm, made by the author, interesting, and asked if any member had had experience in such measurements.

DR. GRAY had noticed much variation in resistance in many of his patients from day to day.

DR. STARR had measured the resistance in Basedow's disease, and had found it to vary within a thousand ohms in the same cases from time to time. Electricity was diffused through muscular better than any other tissue. The chief resistance was in the skin. Probably but little of the current permeated nerves, and hence alterations of nervous tissue would not have much to do with the variations mentioned by the author.

DR. G. M. HAMMOND stated that it was well known that the resistance differs from day to day in animals. He asked if in this case it had been measured for a number of times, and was answered that eight trials had been made.

DR. BIRDSALL thought the question of resistance had little to do with our study of disease. It was easy to explain the numerous variations by the wide differences in vascularity and moisture of the tissues at different times. It might be due, in this case, to paralysis affecting the physical condition of the tissues. The saturation of the epidermis by perspiration would explain the variations mentioned by Dr. Gray. He had made measurements in cases of Basedow's disease some time ago, and believed the diminished resistance found, to be due to the moisture of the skin. It could not depend on dynamic conditions in the nervous system, but was purely a matter of physics about which there was no great mystery.

DR. GRAY said the explanation by moisture of the skin was not applicable in his cases. The differences which he had observed were not owing to the humidity of the atmosphere, although atmospheric conditions might possibly induce dynamic changes in the body.

DR. SACHS pointed out that on one day the author's case showed 580 ohms increase on the diseased side, and on another day 1170 ohms increase on the sound side. Such variations evidently had little to do with the pathological process in the patient. Eulenberg had measured the resistances in cases of paralysis agitans and of Basedow's disease, but without any practical results. As such measurements were very complex they required exceedingly great care.

DR. PRINCE objected to the use of the palm of the hand for precise experimentation, owing to the great variability of the thickness of the skin, and consequently of the resistance. He thought the forearm ought to be used.

DR. LESZYNSKY had not brought forward the question of resistance, in this case, as a diagnostic symptom. It was increased in the affected arm at every examination. With subsidence of the symptoms the resistance gradually diminished, but there was a difference between the sound and morbid side throughout the disease. As to the question of moisture, there was excessive perspiration upon the paralyzed arm, while the normal arm was dry, in spite of which the resistance was greater upon the former. He thought it better to place the electrode upon the wrist than in the hand. There was no antecedent traumatism in the case; the roughening of the shoulder-joint was the result of the paralysis.

DR. M. ALLEN STARR, of New York, then presented a specimen of an

INTERPEDUNCULAR MYXOSARCOMA.

It lay in the middle cranial fossa in the median line, between the crura cerebri, which it separated. It extended into the lateral ventricles, separating widely the caudate nuclei and optic thalami. The patient was a male, aged twenty-one months at death. At the age of thirteen months, in October last, a lateral nystagmus had been observed in both eyes, varying from time to time. Drs. Knapp and Roosa found a slight pallor of the optic disks, which they considered normal. Later, exophthalmos developed, gradually increasing until death. Convergence of the eyes was impossible, although no paralysis of a cranial nerve was discoverable. The reflexes of the iris were lost. Toward the middle of April, this year, the child became unable to walk. The knee-jerks were exaggerated; there was ankle-clonus and typical spastic rigidity. Finally, the back could not be held up, and later the head could not be supported. There was gradual emaciation. There was no apparent headache. From time to time the scalp was congested. About this time the pallor of the optic disks indicated atrophy. There was no blindness, no hemiopia, no aphasia, as far as could be ascertained in so young a child. Toward the middle of May ataxia of the arms developed, but without loss of muscular power. June 8th vomiting and Cheyne-Stokes respiration came on, and the child died in nine hours. The diagnosis of tumor had been made, but the question of localization was of great interest. Nystagmus was not a localizable symptom, but had been found most frequently in lesions of the corpora quadrigemina. The exophthalmos indicated intra-cranial pressure, the gait disturbance led one to think of a cerebellar lesion, while the ataxia of the hands pointed to a basilar trouble affecting, symmetrically, either the pons or the medulla. The question of operative interference had been considered, but he had opposed that proposition because of the difficulty of localizing the tumor. The autopsy proved that the pons was not even pressed upon, and that the cerebellum was normal. There were twenty ounces of fluid in the ventricles. He would ask if there was any localizing value in nystagmus or exophthalmos, and what was the probable cause of the ataxia?

THE PRESIDENT, in referring to the question of ataxia, recalled a case of remarkable bilateral ataxia with optic atrophy, where a large interpeduncular tumor was found between the crura. He thought such ataxia was to be accounted for by pressure upon the motor tracts or motor nuclei. To him the most puzzling feature of Dr. Starr's case was the absence of blindness. As to the nystagmus, it had as yet, in his opinion, no localizing value. He had seen two cases with lesions of the quadrigeminal bodies, but without nystagmus.

DR. LESZYNSKY said the child may have had only central vision, which might explain the presence of nystagmus, but Dr. Starr answered that the visual fields were normal.

DR. SACHS was reminded of Meynert's case of tumor in both optic thalami, with ataxia similar to that of Dr. Starr's case. He thought the thalami might have been pressed upon in the latter, but still was not sure that would cause the ataxia. He considered nystagmus very frequent in many central disorders of children.

DR. H. M. LYMAN referred to a case he had seen re-

cently of defective cerebral development in a child where there was also nystagmus.

DR. GRAY asked how a diagnosis of intra-cranial tumor had been made so early in this case, and was answered that the diagnosis had not been made until all the symptoms described had made their appearance.

DR. HAMMOND thought ataxia depended upon injury to the optic thalami or corpora striata, and referred to a case of Weir Mitchell's, in which there was a remarkable unilateral ataxia with a lesion of the optic thalamus and corpus striatum upon the opposite side.

DR. LESZYNSKY saw a child several years ago with a well-marked nystagmus, which disappeared in the course of time. There was no discoverable cause.

(To be continued.)

CONGRESS OF THE GERMAN SOCIETY OF SURGERY.

Eighteenth Annual Session.
Held at Berlin April 24th to 27th, 1889.

(Concluded from vol. liv. page 695.)

DR. PIETRZIKOWSKI, of Prague, in a paper on

PNEUMONIAS CONSECUTIVE TO STRANGULATED HERNIA.

Comparatively often do we observe pneumonia as a result of inflammation of the peritoneum, and in particular after kelotomy for strangulated hernia. In old people one might think of hypostatic pneumonia, or of a pneumonia due to the penetration of vomited matter into the air-passages; but in another series of facts these two suppositions are not admissible, especially when we have to deal with strong and powerful young men. Gussenbauer thought that these pneumonias were due to partial emboli which started from thrombosed intestinal blood-vessels. If those emboli contain no microörganisms, a simple inflammation is produced which is rapidly cured; but if they are derived from a strangulated loop, they determine deep lesions which end in lobar or lobular pneumonia. If we look over the hospital records we find that this pneumonia is produced in 8 per cent of the cases of operation. But if patients are carefully examined we find light pulmonary manifestations in 30 and even in 50 per cent. of such patients. In the majority of cases the affection is only a simple infarct, and the pulmonary signs disappear in from eight to ten days; in other cases, however, the disease takes the form of pneumonia or pleurisy. Gussenbauer's theory is sustained by this observation, that the pulmonary phenomena come on especially when a strangulation has lasted a very short time. In such cases the clots have not had time to adhere to the parietes. On the contrary, pneumonias are very rare when the strangulated loop has become gangrenous and the circulation has been interfered with. In such cases we must make an abdominal fistula, and in such cases the pneumonia is much more rare than after simple kelotomy. Jaundice is quite a frequent symptom as a result of the reduction of a strangulated hernia; it can also be explained by emboli which have been arrested in the liver; this fact is often confirmed by the post-mortem.

As a result of his experiments on dogs, in which he made artificial strangulated hernias, he found in ten animals on which the operation succeeded, parenchymatous alterations of the lungs and sometimes of the liver, due to emboli enfarcts. In a few cases he was able to demonstrate the formation of a thrombus in the intestinal vessels. The thrombus reaches the lung by the portal venous system and by the inferior vena cava.

DR. THIEM, of Kottbus, had observed on two occasions pulmonary infarcts after the reduction of a hernia; still he did not think it was a special complication, for he had observed the same pulmonary accidents after the total extirpation of the gall-bladder and of the uterus.

PROF. KÜMMEL, of Hamburg, then read a paper on

OPERATIVE TREATMENT OF HYPERTROPHY OF THE PROSTATE GLAND.

He had performed on six patients a partial extirpation of the hypertrophied prostate gland. His cases were very grave, as they had resisted all other methods of treatment. There was fever, bronchitis, and considerable vesicular dilatation. In such cases the operation is indicated, while it is the contrary when the kidneys are seriously involved or when there is a complete paralysis of the bladder. In this last case the operation is useless, for even after the suppression of the obstacle, spontaneous micturition cannot be reëstablished. To extirpate the prostate gland he performs superior cystotomy; the bladder is very carefully washed out, and he then destroys, by the aid of the thermo-cautery, not only the median lobe, but also all the parts of the gland which project into the bladder. He then sutures the bladder, and allows Nélaton's sound to remain in it. Out of six patients, one died from collapse, in another the operative result was negative, four are cured and can urinate spontaneously.

PROF. SOCIN, of Bâle, said that most of the symptoms from which prostatic patients suffer depend, not upon the hypertrophy of the prostate gland, but upon a concomitant vesical catarrh. We know that even very considerable hypertrophies of the prostate gland are sometimes followed by negative symptoms, while very small hypertrophies cause very considerable suffering. All depends on the state of the bladder. If one succeeds in curing the cystitis, most of the troubles disappear, even without interference. The good results which sometimes follow extirpation of the prostate gland, are due probably more to the washing out of the bladder and to the sound left in position—that is, to the treatment of the cystitis—than to the operation itself. The cystitis is the first enemy to combat in the treatment of prostatic patients.

PROF. THIERSCH agreed on every point with Dr. Socin; he, moreover, called attention to the fact that the median lobe of the prostate is sometimes very useful to certain patients, in whom it prevents the outflow of urine by closing the entrance of the urethra; hence the extirpation of the middle lobe can make the patient worse instead of better.

PROF. MIKULICZ then spoke of

TURPENTINE AS AN EXCITANT FOR THE PRODUCTION OF OSSEOUS TISSUE.

He exhibited a patient in whom the whole tibia had become necrosed. Repair had taken place, except for a distance of about two inches, where there existed a large fibrous cicatricial cord containing periosteal remains. He thought of stimulating the vitality of the periosteum and making it reproduce bone in sufficient quantity to remedy the deformity of the limb. To do

this he made in the persistent fibrous cord several longitudinal sections, between the lips of which he interposed turpentined gauze, which was changed every ten days, by this means he obtained a comparatively large bone.

PROF. V. BERGMANN said he had not obtained any good results from employing turpentine, as just recommended.

DR. HAHN, in a similar case to that of Prof. Mikulicz, where the fibula had been saved and two inches of the tibia were absent, implanted the fibula into the tibia.

PISTOL-SHOT WOUND OF THE ABDOMEN.

DR. BRAMANN presented a young man who received a pistol-shot in the left epigastric region. Three hours after the wound he could detect the presence of liquid in the abdominal cavity. The man was seized with collapse. Laparotomy was then performed; the ball had perforated a loop of small intestine and wounded a large artery, which had produced quite a hemorrhage. The artery was ligated. The points of entrance and exit of the ball in the intestine were found absolutely closed by the intestinal mucous membrane; even by pressing on the perforated loop no gas or intestinal contents could be made to come out. No sutures were made; no washing of the abdominal cavity; the blood clots alone were removed. The patient was cured after the first dressing. He thought it unnecessary to use the American method to know if the intestine has or has not been wounded. The method consists in introducing hydrogen gas by the rectum. If the intestine is perforated the hydrogen will come out by this opening into the peritoneal cavity, which it again leaves to come out by the wound which exists in the abdomen to reach the exterior. If this takes place, a lighted match placed at the point of entrance of the ball will light a jet of hydrogen gas, which will demonstrate the perforation.

PROF. SOCIN said that according to experiments made by a French surgeon on dogs which were fasting, the state of the stomach at the time the wound has been inflicted is of the highest importance. It is only when the intestine is empty that the mucous membrane will be able to reverse itself and close the points of entrance and exit of the ball.

Adjourned.

NEWS ITEMS.

Free Libraries and Contagion.—It implies no real disparagement of the great advantages connected with public libraries that books issued by them are occasionally to be found in houses where infectious disease is prevalent. The possibility of risk thus incurred is inevitable unless the system of book-lending throughout the country is to be done away with. A few days ago it was announced in the daily press that four books from a free library had been discovered in a house where one child had fever; and the case, as we know from recent experience, is not singular. Instances of the same kind must have occurred since the earliest period at which books were placed in circulation. Some persons, perhaps, under the guidance of a timid over-zeal for health, might condemn the free library itself as a virtual source of contamination. In our opinion this would be to caricature precaution. With almost equal reason might we forbid to infected households all necessary intercourse with tradesmen who supply their daily wants. The real remedy is not to be found in any superfine theorizing, but in more practical measures. These must include the compulsory notification to librarians of infectious disease among the families of their readers, the thorough disinfection or destruction of books already exposed to the taint of disease, and the temporary restriction of any further issue to the homes of infected persons.—*Lancet*, May 4, 1889.

The British and American Pint.—According to the *British Med. Journal*, the attention of the Midland Counties Chemical Association was lately called to the indeterminate character of the pint measure in use among pharmacists, or, as it was put, the doubt as to the meaning of the abbreviation *Oss.* Our contemporary remarks, however, that all ambiguity ought to have been cleared up by the General Medical Council's distinct statement that twenty fluidounces constitute a pint. Inasmuch as our American apothecaries' pint consists of only sixteen fluidounces, it will be well for prescribers and dispensers to bear the disparity in mind.—*New York Med. Journal*, May 11, 1889.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JUNE 25 TO JULY 1, 1889.

CORSON, J. K., *Major and Surgeon.*—The leave of absence for one month, granted by Par. 2, S. O. 65, *c. s.*, Department of the Columbia, is extended one month.—Par. 1, *S. O. 45, Headquarters Division of the Pacific*, June 24, 1889.

CHAPIN, A. R., *Captain and Assistant Surgeon.*—Is granted leave of absence for twenty-five days, to commence on or about July 2, 1889.—Par. 6, *S. O. 145, Division of the Atlantic*, June 27, 1889,

By direction of the Secretary of War, EZRA WOODRUFF, *Major and Surgeon*, is relieved from temporary duty at Fort Monroe, Virginia, and will report in person to the commanding officer at Fort Hamilton, New York, for duty at that station.—Par. 5, *S. O. 146, A. G. O.*, June 25, 1889.

By direction of the Secretary of War, the extension of leave of absence granted WALTER W. R. FISHER, *Captain and Assistant Surgeon*, in S. O. 41, June 12, 1889, Division of the Pacific, is still further extended fifteen days.—Par. 8, *S. O. 146, A. G. O., Washington*, June 25, 1889.

HOFF, JOHN VAN R., *Captain and Assistant Surgeon.*—Is relieved from duty at Fort Reno, Indian Territory, and ordered to Fort Riley, Kansas.—Par. 6, *S. O. 145, A. G. O., Washington, D. C.*, June 24, 1889.

BACHE, DALLAS, *Major and Surgeon.*—Is relieved from duty at Fort Riley, Kansas, and ordered to report to the commanding general Department of the Platte, for duty as Medical Director of that Department.—Par. 6, *S. O. 145, A. G. O., Washington, D. C.*, June 24, 1889.

By direction of the Secretary of War, leave of absence for two months is granted GEORGE T. BEALE, *Captain and Medical Storekeeper.*—Par. 8, *S. O. 148, A. G. O.*, June 27, 1889.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING JUNE 29, 1889.

SIEGFRIED, C. A., *Surgeon.*—Detached from the U. S. S. "Quinnebaug," and wait orders.

CURTIS, *Passed Assistant Surgeon.*—Detached from the U. S. S. "Quinnebaug," and wait orders.

SMITH, GEORGE T., *Assistant Surgeon* —Ordered to the Army and Navy Hospital, Hot Springs, Arkansas.

ORIGINAL LECTURES.

CONSIDERATIONS CONCERNING SOME EXTERNAL SOURCES OF INFECTION IN THEIR BEARING ON PREVENTIVE MEDICINE.

The Address in State Medicine delivered before the American Medical Association at Newport on June 28, 1889.

BY WILLIAM H. WELCH, M.D.,

PROFESSOR OF PATHOLOGY IN JOHNS HOPKINS UNIVERSITY, BALTIMORE.

No department of medicine has been cultivated in recent years with such zeal and with such fruitful results as that relating to the causes of infectious diseases. The most important of these results for preventive medicine and for the welfare of mankind is the knowledge that a large proportion of the causes of sickness and death are removable.

It is evident that efforts to preserve health will be most intelligently and effectually applied when they are based upon an accurate and full knowledge of the agencies which cause disease. Public and private hygiene, however, can not and, fortunately, has not waited for the full light of that day, whose dawn has only begun to appear, when we shall have a clear insight into the causation of preventable diseases. Cleanliness and comfort demand that means shall be taken to render pure the ground on which we live, the air which we breathe, and the water and food with which we are supplied, and we must meet these needs without waiting to learn just what relation infectious agents bear to the earth, air, water, and food.

It is a fortunate circumstance that modern sanitation has been controlled so largely by the belief in the dependence of endemic and epidemic diseases upon organic impurities in the soil and in the water. Incomplete and even erroneous in many respects as are the views which have prevailed concerning the origin and spread of epidemic diseases by the decomposition of organic substances, the sanitary measures which have been directed toward the removal of filth have achieved great conquests in limiting the development and extension of many infectious diseases. The benefits which one Commonwealth of this country has derived from the intelligent employment of public sanitary measures were clearly and forcibly presented before this Association last year by Dr. Walcott, in his admirable address in State Medicine.

While nothing should be said or need be said to lessen the importance of cleanliness for public health, it is important to bear in mind that hygienic cleanliness and æsthetic cleanliness are not identical. In water which meets the most severe chemical tests of purity, typhoid bacilli have been found. On the other hand, the air in the Berlin sewers, which certainly does not meet the most modest demands of æsthetic cleanliness, has been found to be nearly or quite free from bacteria.

It needs only to be stated to be generally admitted that the scientific basis of preventive medicine must be the accurate knowledge of the causative agents of preventable diseases, a knowledge which can be derived only from a careful study of all the properties of these agents, the modes of their reception and of their elimination by the body, the circumstances which favor and those which retard or prevent their development and spread, their behavior in the various substances which surround us or which we take into our bodies, and the sources of infection, not only those which laboratory experiments show to be possible, but those which are actually operative.

So long as we were unacquainted with the living organisms causing infection, the means at our disposal for studying the etiology of infectious diseases were limited to the observation of all the circumstances which we could determine regarding the origin and spread of these diseases. We could only infer what might be the properties of the infectious agents from the study of phenomena often obscure and difficult of interpretation. Chiefly by this method of investigation the science of epidemiology has been built up. It has established facts and laws no less of practical than of scientific importance. But it has left unsolved many problems and has filled gaps with speculations. Admitted epidemiological facts are often open to various interpretations.

We are evidently at a great advantage when we can study the epidemiological facts with a knowledge of the substances which actually cause infection, and this we are now enabled to do for a limited number of the infectious diseases. This new method of research, which thus far has been mainly bacteriological, has aided us not so much by simplifying the problems of etiology, which still remain complicated enough, as by affording greater accuracy to the results.

It is my aim in this address to consider some results of the modern studies of pathogenic microörganisms in their bearing upon preventive medicine, more particularly upon the sources of infection. It is, of course, impossible within the limits of the address to attempt a complete survey of this important field. Time will permit the presentation of only some of the salient points.

Infectious diseases are those which are caused by the multiplication within the body of pathogenic microorganisms.

It has always been recognized that some infectious diseases, such as the exanthematous fevers, are conveyed directly from the sick to the healthy. It is not disputed that in these evidently contagious diseases the infectious germ is discharged from the body in a state capable at once of giving rise to infection.

In a second group of infectious diseases, of which malaria is the type, the infected individual neither trans-

mits the disease to another person, nor, so far as we know, is capable of infecting a locality. Here there is reason to believe that the infectious germ is not thrown off in a living state from the body, but is destroyed within the body. In this group the origin of infection under natural conditions is always outside of the body.

In a third group there is still dispute whether the disease can be transmitted directly from person to person, but all are agreed that the infected individual can infect a locality. It is especially fortunate that the bacteria which cause cholera and typhoid fever, the two most important representatives of this group of so-called miasmatic-contagious diseases, have been discovered and isolated in pure culture. These are the diseases about whose origin and epidemic extension there has been the greatest controversy. They, above all other diseases, have given the impulse to public sanitation during the last half century. The degree of success with which their extension in a community is prevented is an important gauge of the excellence of the local sanitary arrangements. A clear comprehension of the origin and spread of these diseases signifies the solution of many of the most vexed and important problems of epidemiology and of State hygiene.

It is difficult to understand how those who accept the discovery that the bacteria causing typhoid fever and cholera have been found and cultivated from the stools of patients affected with these diseases can doubt that these patients are possible sources of contagion, or can entertain the view once so widely prevalent, that the infectious germs of these diseases are discharged from the body in a condition incapable of producing immediate infection. In an address delivered on another occasion, I have endeavored to present the considerations which reconcile the comparative infrequency of direct contagion for these diseases with the belief in the elimination of the causative germs in an active state from the body, and have there pointed out several well-known factors which determine the frequency of conveyance of an infectious disease by contagion. There are reasons, some of them very obvious, why diseases in which the infectious substances are operative only when received into the digestive tract, and are discharged usually only with the feces, are less likely to be transmitted by immediate contagion than those diseases in which the virus is thrown off from the skin on epidermal scales.

But the field of operation of direct contagion for these so-called miasmatic-contagious diseases is at most a restricted one, and the chief sources of infection are outside of the body from which primarily the infectious germs may have been derived. It is to these external sources of infection, which are of such importance in public hygiene, that I wish especially to direct attention.

A full comprehension of the sources of infection is, of course, to be obtained only by a detailed study of the etiology of the individual infectious diseases, but this is impossible within the limits of an address. It may, however, be useful to present some of the facts which have a general bearing upon the subject. Let us consider, then, from the point of view of modern bacteriological studies, what *rôle*, in harboring or in transporting infectious agents, may be played by those substances or media with which we necessarily come into intimate contact, such as the air, the ground, the water, and our food.

It is universally admitted that many infectious agents may be transported by the air, but the extent of danger from this source has often been exaggerated. It is a popular error to suppose that most of the minute particles of dust in the air either are or contain living organisms. The methods for determining the number and kind of bacteria and fungi in the air are now fairly satisfactory, although by no means perfect. These have shown that while the number of living bacteria and fungi in the atmosphere in and around human habitations cannot be considered small, still it is greatly inferior to that in the ground or in most waters. Unlike fungus spores, bacteria do not seem to occur to any extent in the air as single detached particles, which would then necessarily be extremely minute, but rather in clumps or attached to particles of dust of relatively large size. As a result in a perfectly quiet atmosphere these comparatively heavy particles which contain bacteria rapidly settle to the ground or upon underlying objects, and are easily filtered out by passing the air through porous substances, such as cotton-wool, or sand. Rain washes down a large number of bacteria from the air.

That the air bacteria are derived from the ground, or objects upon it, is shown by their total absence, as a rule, from sea air at a distance from land, this distance naturally varying with the direction and strength of the wind.

A fact of capital importance in understanding the relations of bacteria to the air, and one of great significance for preventive medicine, is the impossibility of currents of air detaching bacteria from moist surfaces. Substances containing pathogenic bacteria, as, for instance, sputum containing tubercle bacilli or excreta holding typhoid bacilli, cannot, therefore, infect the air unless these substances first become dry and converted into a fine powder. We are able to understand why the expired breath is free from bacteria and cannot convey infection, except as little particles may be mechanically detached by acts of coughing, sneezing, or hawking. Those bacteria, the vitality of which is rapidly destroyed by complete desiccation, such as those of Asiatic cholera, evidently are not likely to be transported as infectious agents by the air, if we except such occasional occurrences as their conveyance for a short distance in spray.

The only pathogenic bacteria which hitherto have been found in the air are the pus organisms, including the streptococcus found by Prudden in a series of cases of diphtheria, and tubercle bacilli; but no far-reaching conclusions can be drawn from the failure to find other infectious organisms when we consider the imperfection of our methods and the small number of observations directed to this point. The evidence in other ways is conclusive that many infectious agents—and here the malarial germ should be prominently mentioned—can be and often are conveyed by the air. While we are inclined to restrict within narrower limits than has been customary the danger of infection through the air, we must recognize that this still remains an important source of infection for many diseases. All those, however, who have worked practically with the cultivation of microorganisms have come to regard contact with infected substances as more dangerous than exposure to the air, and the same lesson may be learned from the methods which modern surgeons have found best adapted to prevent the infection of wounds with the cosmopolitan bacteria which cause suppuration.

We are not, of course, to suppose that infectious germs

floating in the form of dust in the atmosphere are dangerous, only from the possibility of our drawing them in with the breath. Such germs may be deposited on substances with which we readily come into contact, or they may fall on articles of food where they may find conditions suitable for their reproduction, which cannot occur when they are suspended in the air in consequence of the lack of moisture.

From the facts which have been mentioned concerning the relations of bacteria to the air, what points of view present themselves to guide us in preventing infection through this channel? Surely something more than that this purpose is accomplished simply by abolishing foul odors.

Certain indications are so plain as to need only to be mentioned in this connection, such as the disinfection and removal, as far as possible, of all infected substances, an indication which applies equally to all channels of infection, and which it is much easier to mention than it is to describe how it shall be realized. But there are two indications which apply especially to the prevention of the transportation of disease germs by the air. One is the necessity of guarding, as far as practicable, against the desiccation, when exposed to the air, of substances which contain infectious germs not destroyed by drying, and another is free ventilation.

For no disease is the importance of the first of these indications so evident and so well established as for tuberculosis, the most devastating of all infectious diseases. Against this disease, formidable as it may seem to cope with it, the courageous crusade of preventive medicine has begun, and is destined to continue.

It is now generally recognized that the principal, although not the sole, sources of tuberculous infection are the sputum of individuals affected with pulmonary tuberculosis and the milk of tuberculous cows. Cornet, who has made a laborious and most instructive experimental study of the modes and dangers of infection from tuberculous sputum, has also elaborated the practical measures which should be adopted to diminish or annihilate these dangers. These measures have been so recently and so widely published in medical journals, and so clearly presented before a section of this Association, that I mention them only to call the attention of practitioners of medicine to their importance, and to emphasize the fact that infectious substances of such nature as tuberculous sputum should not be allowed to become dry and converted into dust when exposed to the air.

By means of free ventilation, disease-producing microorganisms which may be present in the air of rooms are carried away and distributed so far apart that the chance of infection from this source is removed or reduced to a minimum. It is a well-established clinical observation that the distance through which the specific microbes of such diseases as smallpox or scarlatina are likely to be carried from the patient by the air, in such concentration as to cause infection, is small, usually not more than a few feet, but increases by crowding of patients and absence of free ventilation. The well-known experiences in the prophylaxis and treatment of typhus fever are a forcible illustration of the value of free ventilation.

It is, of course, not to be understood that by ventilation we accomplish the disinfection of a house or apartment. Ventilation is only an adjunct of such disinfection which, as already mentioned, is of first importance. Time will not permit, nor is it in the plan of this address, to discuss the details of such questions as house disinfection, but I may be permitted to say that the methods for disinfecting apartments have been worked out on a satisfactory experimental basis and should be known at least by all public health officers. Whether it be pertinent to this occasion or not, I cannot forbear to add my protest to that of others against placing reliance upon any method hitherto employed of disinfecting houses or apartments by fumigation. And I would, furthermore, call attention to the lack in most cities of this country of public disinfecting establishments such as are in use with excellent results in many cities of Europe, and which are indispensable for the thorough and convenient disinfection of clothing, bedding, carpets, curtains, etc.

After this short digression let us pass from the consideration of the air as a carrier of infection to another important external source of infection, namely, the ground. That the prevalence of many infectious diseases depends upon conditions pertaining to the soil cannot be questioned, but the nature and extent of this influence have been and are the subjects of lively discussion. The epidemiological school led by Pettenkofer assigns, as is well known, to the ground the chief and even a specific and indispensable influence in the spread of many epidemic diseases, particularly cholera and typhoid fever. The statistics, studies, and speculations of epidemiologists which have related to this subject probably surpass in number and extent those concerning any other epidemiological factor. The exclusive ground hypothesis has become an ingenious and carefully elaborated doctrine with those who believe that such diseases as cholera and typhoid fever can never be transmitted by contagion. These authorities cling to this doctrine with a tenacity which indicates that on it depends the survival of the exclusively localistic dogma for these diseases.

To all who have not held aloof from modern bacteriological investigations it must be clear that views which have widely prevailed concerning the relations of many infectious germs to the soil require revision. The question is still a difficult and perplexing one, but on some hitherto obscure or misunderstood points these investigations have shed light, and from the same source we may expect further important contributions to a comprehension of the relations of the ground to the development of infectious diseases.

The ground, unlike the air, is the resting or the breeding place of a vast number of species of microörganisms, including some which are pathogenic. Instead of a few bacteria or fungi in a litre as with the air, we find in most specimens of earth thousands, and often hundreds of thousands, of microörganisms in a cubic centimetre. Frānkel found the virgin soil almost as rich in bacteria and fungi as that around human habitations.

This vast richness in microörganisms belongs, however, only to the superficial layers of the earth. Where the ground has not been greatly disturbed by human hands there is, as a rule, about three to five feet below the surface an abrupt diminution in the number of living organisms, and at the depth where the sub-soil water usually lies, bacteria and fungi have nearly or entirely disappeared. Frānkel, who first observed this sudden diminution in the number of microörganisms at a certain level beneath the surface, explains this singular fact by

the formation at this level of that sticky accumulation of fine particles consisting largely of bacteria which forms the efficient layer in large sand filters for water. Of course, the number of bacteria and the depth to which they penetrate will vary somewhat with the character, especially the porosity, of the soil and its treatment, but the important fact that all, or nearly all, of the bacteria and fungi are retained in the ground above the level of the sub-soil water will doubtless hold true for most situations.

The conditions are not favorable for the multiplication of bacteria in the depth of the ground, as is shown by the fact that in specimens of earth brought to the surface from a depth of a few feet, the bacteria which are at first present, rapidly multiply. What all of the conditions are which prevent the reproduction of bacteria in the deep soil has not been ascertained, but the fact necessitates similar precautions in the bacteriological examination of the soil as in that of water.

We have but meagre information as to the kinds of bacteria present in the ground in comparison with their vast number. Many of those which have been isolated and studied in pure culture possess but little interest for us so far as we know. To some of the microörganisms in the soil appears to be assigned the *rôle* of reducing or of oxidizing highly organized substances to the simple forms required for the nutrition of plants. We are in the habit of considering so much the injurious bacteria that it is pleasant to contemplate this beneficent function so essential to the preservation of life on this globe.

Among the pathogenic bacteria which have their natural home in the soil, the most widely distributed are the bacilli of malignant œdema and those of tetanus. I have found some garden earth in Baltimore extremely rich in tetanus bacilli, so that the inoculation of animals in the laboratory with small bits of this earth rarely fails to produce tetanus. In infected localities the anthrax bacillus and in two instances the typhoid bacillus, so far as it was possible to identify it, have been discovered in the earth. There is reason to believe that other germs infectious to human beings may have their abiding place in the ground; certainly no one doubts that the malarial germ lives there. As the malarial germ has been shown to be an organism entirely different from the bacteria and the fungi, we cannot apply directly to its behavior in the soil and its transportation by the air, facts which have been ascertained only for the latter species of microörganisms, and the same precautions must be observed for other diseases with whose agents of infection we are not acquainted, as, for instance, yellow fever.

In view of the facility with which infectious germs derived from human beings or animals may gain access to the soil, it becomes a matter of great importance to determine how far such germs find in the soil conditions favorable for their preservation or their growth. We have, as is well known, a number of epidemiological observations bearing upon this subject, but with few exceptions these can be variously interpreted, and it is not my purpose to discuss them. The more exact bacteriological methods can, of course, be applied only to the comparatively small number of infectious diseases, the causative germs of which have been isolated and cultivated, and these methods hitherto have been applied to this question only imperfectly. We cannot regard the soil as a definite and unvarying substance in its chemical, physical, and biological properties. What has been found true of one kind of soil may not be so of another.

Moreover, we cannot in our experiments bring together all of the conditions in nature which may have a bearing on the behavior of specific microörganisms in the soil. We must, therefore, be cautious in coming to positive conclusions on this point on the basis of experiments, especially those with negative results. With these cautions kept constantly in mind the question, however, is one eminently open to experimental study.

The experiments which have thus far been made to determine the behavior of infectious microörganisms in the ground have related especially to the bacilli of anthrax, of typhoid fever, and of cholera, and, fortunately, these are the diseases about whose relations to the ground there has been the most discussion and concerning which we are most eager to acquire definite information.

As regards anthrax bacilli, it has been determined that in ordinary garden or field earth they do not multiply, but in earth contaminated by blood, urine, or feces their reproduction can occur. They can grow on various vegetable substrata. There is no reason to doubt, therefore, that the anthrax bacilli can find in or on the ground suitable conditions for their multiplication, although such conditions are not everywhere present. For durable infection of the soil with anthrax bacilli it is, however, more important that these bacilli should find there suitable conditions for the formation of spores, than that they should be able simply to multiply. The vegetative forms of anthrax bacilli would not, as a rule, be able to survive for a great length of time the hostile influences which they are likely to encounter in the ground, such as insufficient or exhausted nutriment, absence of sufficient moisture, and the attacks of saprophytic organisms. On the other hand, against these injurious influences the anthrax spores have great resistance. In the superficial layers of the ground the anthrax bacilli may often find those conditions of moisture, of temperature, of oxygen supply, and of insufficient food which we know are most favorable for the development of their spores; indeed, Soyka has shown that the ground presents often these conditions better than our culture media. A circumstance discovered by Feltz, which, however, needs confirmation, is, if true, of not little significance. He finds that anthrax bacilli may undergo a progressive diminution in virulence in the soil. If this should be true likewise of other infectious microörganisms, we should be able to account, in some instances, for the variable degree of virulence which clinical observation indicates that certain agents of infection acquire. So far as anthrax bacilli are concerned we may conclude, therefore, that the ground occasionally offers suitable conditions for their reproduction, but what is of greater importance, it offers especially favorable conditions for their long-continued preservation in the form of spores. I must forego here the further consideration of the special circumstances inherent in the soil which control the origin and spread of epidemics of anthrax in cattle, although many interesting investigations have been directed to this subject.

Of greater interest to physicians is the behavior of typhoid and of cholera bacteria in the ground. As has already been intimated the ground is regarded by Pettenkofer and his school as the principal breeding-place

of these microörganisms outside of the body. This view, however, is not supported by bacteriological investigations. Inasmuch as the cholera and the typhoid bacilli may multiply on various vegetable substrata and substances derived from animals, at temperatures often present in the ground, it is evident that here and there conditions may be present for their growth in the ground, but this growth is likely to be soon interrupted by the invasion of ordinary saprophytic organisms and other harmful influences. The typhoid bacilli are more hardy in resisting these invaders than are the cholera bacteria, which easily succumb, but even for the former, so far as our present knowledge extends, the ground can rarely serve as a favorable breeding-place.

It is not, however, necessary that these organisms should multiply in order to infect for a considerable time the ground; it is sufficient if their vitality is preserved. As to this latter point, the reports of different investigators are not altogether concordant. Such excellent observers as Koch, Kitasato, and Uffelmann found that the cholera bacteria, when added to feces or a mixture of feces and urine, rapidly diminished in number, and at the end of three, or four days at the most, had wholly disappeared. In a mixture of the intestinal contents from a cholera corpse with earth and water Koch found numerous cholera bacteria at the end of three days, but none at the end of five days. On the other hand, Gruber reports the detection of cholera bacteria in cholera dejecta fifteen days old. The weight of bacteriological evidence, therefore, is opposed to the supposition that the bacteria of Asiatic cholera preserve their vitality for any considerable time in the ground or in the excreta.

With respect to the bacilli which cause typhoid fever, it has been shown by Uffelmann that these may live in feces, mixture of feces and urine, and mixture of garden earth, feces, and urine for at least four and five months, and doubtless longer, although they may die at the end of a shorter period. He also finds that under these apparently unfavorable conditions some multiplication of the bacilli may occur, although not to any considerable extent. Grancher and Deschamps found that typhoid bacilli may live in the soil for at least five months and a half. Unlike the cholera bacteria, therefore, the typhoid bacilli may exist for months at least in the ground and in the fecal matter, holding their own against the growth of multitudes of saprophytes. This difference in the behavior of cholera and of typhoid germs is in harmony with clinical experience.

As regards other infectious bacteria than those which have been considered, I shall only mention that tubercle bacilli, although incapable of multiplication under the ordinary conditions of nature outside of the body, may preserve their vitality for a long period in the ground, on account of their resistant character, and, furthermore, that the pyogenic cocci, on account of their considerably resistant nature and their modest demands in the way of nutriment, can be preserved and sometimes probably grow in the ground. Indeed, the staphylococcus pyogenes aureus has been found in the earth by Lübbert.

The conclusion which we may draw from the observations mentioned is that, in general, the soil is not a good breeding-place for most of the infectious bacteria with which we are acquainted, but that it can retain for a long time with unimpaired vitality those which produce spores or which offer considerable resistance to injurious agencies, such as anthrax bacilli, tubercle bacilli, and the pyogenic cocci.

In order to become infected with bacteria in or on the ground, these bacteria must in some way be introduced into the body and we must, therefore, now attempt to determine how bacteria may be transported to us from the ground. So various and intricate are the possibilities for this transportation that it is hopeless to attempt to specify them all.

There occurs to us first the possibility of the conveyance of infectious microörganisms from the soil by means of currents of air, a mode of carrying infection which has already been considered. Here I shall only repeat that the wind can remove bacteria from the ground only when the surface is dry and presents particles of dust, and that the sole, and perhaps the chief, danger is not that we may inhale the infected dust.

Manifold are the ways in which we may be brought into contact with infectious bacteria in the ground, either directly, or indirectly by means of vegetables to which particles of earth are attached, by the intervention of domestic animals, by the medium of flies or other insects, and in a variety of other ways, more or less apparent.

An important, doubtless for some diseases the most important, medium of transportation of bacteria from an infected soil is the water which we drink or use for domestic purposes. From what has been said, it is evidently not the sub soil water which is dangerous, for infectious like other bacteria cannot generally reach this in a living state, but the danger is from the surface water and from that which trickles through the upper layers of the ground, as well as from that which escapes from defective drains, gutters, cesspools, privy vaults, and wrongly constructed sewers, or improper disposal of sewage. I shall have something to say presently of water as a source of infection and shall not further elaborate here the dangers of infection of drinking water through contaminated soil, dangers which, especially as regards typhoid fever, are widely appreciated in this country, even if often imperfectly counteracted.

A point which has been much discussed and one of interest, is whether bacteria which are in the depth of the ground can come to the surface. Two agencies especially have been considered by some as capable of transporting bacteria from the depth to the surface. One is ascending currents of air in the ground and the other is the capillarity of fluids in the minute pores of the ground. The first of these suspected agencies must be unquestionably rejected in view of the fact that even a few inches of sand is sufficient to filter all of the bacteria out of the air, even when it is in much more rapid motion than can occur within the ground. Moreover, that degree of dryness which is essential for the detachment of bacteria by air-currents is not likely to be present much below the surface of the ground. The experiments which have been made to determine to what extent bacteria may be carried upward by the capillarity of fluids in the ground have not yielded harmonious results, but the weight of evidence is opposed to the belief that this is a factor of any considerable importance for this purpose.

From what has been said concerning the growth of pathogenic bacteria in the soil we shall not be inclined to attribute to the multiplication and the motility of these organisms much influence in changing their place in the ground.

The somewhat sensational role assigned by Pasteur to earthworms of bringing bacteria to the surface cannot be wholly ignored and has received support from observations of Bollinger regarding anthrax, but it is questionable whether much importance is to be attached to this agency.

Regarding the depth to which typhoid bacilli may penetrate the soil, the experiments of Grancher and Deschamps show that at the end of five weeks they may reach a depth of sixteen to twenty inches below the surface. As Hoffmann has demonstrated the extraordinary slowness with which fluids and fine particles penetrate the soil, it is probable that in the course of time a greater depth than this may be reached. Indeed, Macé claims to have found in soil in the neighborhood of a well, suspected of infection, typhoid bacilli, together with ordinary intestinal bacteria, at a depth of at least six and one-half feet below the surface. There are a number of instances recorded in which there is reason to believe that turning up the soil and cleaning out privies or dung-heaps in which typhoid stools have been thrown, have given rise to typhoid fever, even after the infectious excreta have remained there a year and more.

It can not be said that bacteriological investigations have as yet shed much light upon a factor which plays a great *rôle* in epidemiology, namely, predisposition to infection from the ground according to locality and time, and this deficiency receives constant and vehement emphasis from the localistic school of epidemiologists. We can, however, readily understand that varying conditions, such as temperature, moisture, porosity, quality of soil, may exert a controlling influence in determining the behavior of infectious germs in the soil and the facility of their transportation to human beings or animals. As regards that much-discussed question, the significance of variations in the height of the sub-soil water in relation to the prevalence of certain epidemic diseases, particularly cholera and typhoid fever, we now know that this can not depend upon the presence of bacteria in the sub-soil water itself or in the capillary layers immediately above it. It has been plausibly suggested that with the sinking of the sub-soil water fluids from infected cesspools, privy vaults, and other localities may more readily be drawn into wells or other sources of water supply, and that by the same cause the surface of the ground becomes dry so that dust particles may be lifted by the wind. Other more or less plausible explanations have also been offered, but it must be confessed that our positive information on this point is meagre. There can, however, be little doubt that this significance of the variations in sub-soil water is apparent only for certain localities and has been considerably exaggerated and often misunderstood. It is not, however, pertinent to my theme to discuss this or other purely epidemiological observations concerning the relations of the ground to the spread of epidemic diseases, interesting and important as are many of these observations.

Before leaving the subject of the ground as a source of infection, permit me to indicate briefly some conclusions which may be drawn from what has been said as to the principles which should guide us in preventing infection directly or indirectly from the ground.

First in importance is to keep infectious substances as far as possible from the ground. This implies the early disinfection or destruction of such substances as typhoid and cholera excreta and tuberculous sputum.

Second. The ground should be rendered as far as practicable unsuitable for the continued existence of infectious germs. This, at least for some diseases, is accomplished by a proper system of drainage, which, moreover, for other reasons possesses hygienic importance.

Third. Means should be provided to prevent waste products from getting into the ground around human habitations or from gaining access to water used for drinking or domestic purposes. In cities this can be accomplished only by a properly constructed system of sewers. The system of storing waste products in cesspools whence they are to be occasionally removed can not be approved on hygienic grounds. There are conditions in which the disposal of waste products in deep wells only used for this purpose and whence these products can filter into the deep layers of the ground may be permissible, but this can never be considered an ideal method of getting rid of excrementitious substances and is wholly wrong in regions where wells are used for drinking water. But I am trespassing with these remarks upon a province which does not belong to me but rather to practical sanitarians and engineers. I shall only add that the advantage gained by preventing organic waste from soaking into the ground is not so much that the ground is thereby rendered better adapted to the existence of infectious microörganisms, but is due rather to the fact that this waste is likely to contain infectious germs.

Finally, in cities, good pavements, absence of unnecessary disturbance of the soil, cleanliness of the streets, and laying of dust by sprinkling, are not only conducive to comfort but are sometimes hygienically important in preventing infection from the ground and dust.

In passing from the consideration of the ground to that of water, one feels that he now has to do with a possible source of infection against which in this country and in England he is at liberty to make any accusation he chooses without fear of contradiction. There is reason to believe that such accusation has been repeatedly made without any proof of misdemeanor on the part of the water. It is not, therefore, with any desire to awaken further the medical or the public conscience that I wish to say a few words concerning the behavior of bacteria in water and the dangers of infection from this source. That such dangers are very real, must be apparent when we consider the universal employment of water and its exposure to contamination from all kinds of sources.

Ordinary water, as is well known, contains bacteria in large number. Not a few species of bacteria can multiply rapidly and to a large amount even in distilled water. These are the so-called water-bacteria, and, like most of the microörganisms found in ordinary drinking water, are perfectly harmless saprophytes. What we wish to know is, how pathogenic microörganisms conduct themselves in water. Can they grow or be preserved for any length of time in a living condition in water? As regards the multiplication of pathogenic bacteria in water, the results of different experimenters do not altogether agree. Whereas, Bolton failed to find any growth, but rather a progressive diminution in number of pathogenic bacteria planted in sterilized water, Wolff-

hügel and Riedel observed a limited reproduction of such bacteria, including those of typhoid fever and of cholera. This difference is due probably to the methods of experimentation employed. According to Kraus, these latter bacteria diminish rapidly in number in unsterilized spring or well water kept at a low temperature. These experiments indicate that water, even when contaminated with more organic impurities than are likely ever to be present in drinking water, is not a favorable breed ng-place for pathogenic bacteria. Still, it is to be remembered that these laboratory experiments do not reproduce exactly all of the conditions in nature, and it may happen that in some nook, or cranny, or vegetable deposit at the side of a well or stream some pathogenic bacteria may find suitable conditions for their multiplication.

But, as has been repeatedly emphasized in this address, it is not necessary that pathogenic bacteria should actually multiply in a medium in order to render it infectious. It is sufficient, if their life and virulence are not destroyed in a very short time. As to this important point, Bolton found that in sterilized water typhoid bacilli may preserve their vitality for over three months, and cholera bacteria for eight to fourteen days, while Wolffhügel and Riedel preserved the latter in water for about eighty days. Under natural conditions, however, these organisms are exposed to the overgrowth of the water bacteria, so that Kraus found in unsterilized water kept at a temperature of 10.5° C. (50.9° F.), the typhoid bacilli no longer demonstrable after seven days, and the cholera bacteria after two days. The conditions in Kraus's experiments were as unfavorable as possible for the continued existence of these pathogenic bacteria, more unfavorable than those often present at the season of prevalence of cholera and typhoid fever; nevertheless, I do not see that the experimental results justify the conclusions of Kraus as to the slight probability of drinking water ever conveying infection with the germs of typhoid fever and of cholera. To render such a conclusion probable it would be necessary to demonstrate a much shorter preservation than even Kraus himself found. In judging this question it should not be overlooked that infection of drinking water with the typhoid or the cholera germs is not so often the result of throwing typhoid or cholera stools directly into the source of water supply, as it is the consequence of leaky drains, cesspools, privy-vaults, or infected soil, so that there may be continued or repeated accessions of infected material to the water.

In view of the facts presented, there is no sufficient reason, therefore, from a bacteriological point of view, of rejecting the transmissibility of typhoid fever and cholera by the medium of the drinking-water. This conclusion seems irresistible when we call to mind that Koch once found the cholera bacteria in large numbers in the water of a tank in India, and that the typhoid bacilli have been repeatedly found in drinking water of localities where typhoid fever existed. Nor do I see how it is possible to interpret certain epidemiological facts in any other way than by assuming that these diseases can be contracted from infected drinking water, although I know that there are still high authorities who obstinately refuse to accept this interpretation of the facts.

In this connection it may be mentioned that pathogenic bacteria may preserve their vitality longer in ice than in unsterilized drinking water. Thus, Prudden found typhoid bacilli still alive which had been contained in ice for one hundred and three days.

When we come to consider the ways in which water may become infected with pathogenic microörganisms we recognize at once a distinction, in this respect, between surface water and sub-soil water. Whereas the sub-soil water may be regarded under ordinary circumstances and in most places as germ-free, the surface water, such as that in rivers and streams, is exposed to all manner of infection from the ground, the air, and the direct admission of waste substances. Unfortunately, in the ordinary way of obtaining sub-soil water for drinking purposes, by means of dug wells, this distinction is obliterated, for the water which enters these wells free from bacteria is converted into a surface water often exposed, by the situation of the well, to more dangerous contamination than other surface waters used for drinking purposes.

Now let us turn our attention, as we have done with other sources of infection, to a brief outline of certain general principles which may help us in avoiding infection from the water.

We shall, in the first place, avoid as far as possible the use of water suspected of infection, especially with the germs of such diseases as typhoid fever and cholera. When it is necessary to use this suspected water it should be boiled.

As regards the vital question of water supply, it may be stated as a general principle that no hygienic guarantee can be given for the purity of surface water which has not been subjected to a proper system of filtration, or for the purity of spring or well water fed from the sub-soil unless such water is protected from the possibility of infection through the upper layers of the soil or from the air. This is not saying that water which meets certain chemical and biological tests, and which is so situated that the opportunities for its contamination appear to be absent or reduced to a minimum, is not admissible for the supply of drinking water, but the possibility of infection can be removed only by the fulfilment of the conditions just named, and upon these conditions the hygienic purist will always insist.

Unfortunately, we have at present no domestic filters which are satisfactory, and most of those in common use are worse than none, as they soon furnish a filtrate richer in bacteria than the original water. The only effective method of water-filtration for the general supply is by means of large sand filters, such as are in use with excellent results in Berlin and some other cities. These require skilled attention. I cannot on this occasion discuss the construction or working of these filters, but would refer those who are interested to the full and careful investigations of the Berlin filters by Wolffhügel and by Plagge and Proskauer.

What is accomplished by these artificial sand filters is accomplished under natural conditions also by the ground, which furnishes a sub-soil water free from microorganisms, and to obtain pure water we have only to devise means by which this sub-soil water may be secured without the chance of contamination. Just as the water, which has passed through the sand filters, is collected in suitable reservoirs and is distributed in pipes, which do not admit contamination from without, so by means of properly constructed artesian or driven wells we may

secure the naturally filtered sub-soil water with the same freedom from the chances of infection.

It is well to bear in mind that no biological or chemical tests of water can replace those measures which have been mentioned as necessary to secure purity of water supply. These tests are of value only when applied with proper precautions and with due consideration of the special circumstances of each case for which they are employed.

There has been much profitless discussion as to whether greater significance is to be attached to the chemical or to the bacteriological examination of water. Each has its own special field of application, and in this the one cannot replace the other method. The bacteriological examination has for hygienic purposes the advantage that it may enable us to detect the specific agents of infection in the form of microörganisms, as has already been done for cholera bacteria and typhoid bacilli, but this is a comparatively rare result and does not at present afford a wide field of application for this method. The significance of the bacteriological test is to be based more frequently upon the fact that it concerns itself with the same class of microörganisms to which some of the recognized and doubtless many of the undiscovered infectious agents belong, and from the behavior of which in some respects conclusions can be drawn as to the behavior of the pathogenic organisms. Thus the bacteriological test is the only one which enables us to judge correctly of the efficacy of those methods of filtration of surface water and of construction of wells which insure purity of water supply. The points of view from which we can estimate correctly, according to our present knowledge, the relative merits and fields of application of the chemical and of the bacteriological methods of water examination have been clearly indicated by Plagge and Proskauer and by Wolffhügel. The theme is one beyond the limits or the scope of this discourse, and I have referred to it chiefly to emphasize the fact that we cannot rely upon chemical or bacteriological tests of water to the exclusion of those protective measures which have been mentioned, although I do not intend to imply that each of these tests when properly employed does not afford important information and is not of great value in many cases.

I have already taxed so largely your time and patience that I must pass over with brief mention the food as a source of infection. Unlike those external sources of infection, which we have hitherto considered, many articles of food afford an excellent nutritive medium for the growth of a number of species of pathogenic microorganisms, and in many instances this growth may be abundant without appreciable change in the appearance or taste of the food.

When we consider in how large degree the certainty and the severity of infection with many kinds of pathogenic microörganisms depend upon the number of such organisms received into the body, we can appreciate that the danger of infection from food which contains a mass of growing pathogenic bacteria may be much greater than that resulting from the reception of infected water or air, media in which infectious organisms are rarely present in other than a very dilute condition. The entrance into the body of a single infectious bacterium with the inspired air is, at least in the case of many diseases, not likely to cause infection; but let this bacterium fall upon some article of food, as for instance upon milk, where it can multiply in a short time at a favorable temperature many thousand fold, and evidently the chances of infection become vastly increased.

Among the various agencies by which infectious organisms may gain access to the food may be mentioned the deposition of dust conveyed by the air, earth adhering to vegetables, water used in mixing with or in the preparation of food, in cleansing dishes, cloths, etc., and contact in manifold other ways with infected substances.

Fortunately, a very large part of our food is sterilized in the process of cooking shortly before it is partaken, so that the danger of infection from this source is greatly diminished and comes into consideration only for uncooked or partly cooked food and for food which, although it may have been thoroughly sterilized by heat, is allowed to stand considerable time before it is used. Milk, in consequence of its extensive employment in an unsterilized state and of the excellent nutritive conditions which it presents to many pathogenic bacteria, should be emphasized as especially liable to convey certain kinds of infection—a fact supported not less by bacteriological than by clinical observations. Hesse found that also a large number of ordinary articles of food prepared in the kitchen in the usual way for the table and then sterilized afford a good medium for the growth and preservation of typhoid and cholera bacteria, frequently without appreciable change in the appearance of the food.

Upon solid articles of food bacteria may multiply in separate colonies so that it may readily happen that only one or two of those who partake of the food eat the infected part, whereas with infected liquids, such as milk, the infection is more likely to be transmitted to a larger number of those who are exposed.

In another important particular the food differs from the other sources of infection which we have considered. Not only the growth of infectious bacteria, but also that of bacteria incapable of multiplication within the body may give rise in milk and other kinds of food to various ptomaines, products of fermentation, and other injurious substances which when ingested are likely to cause more or less severe intoxication, or to render the alimentary tract more susceptible to the invasion and multiplication of genuinely infectious organisms.

It is plain that the liability to infection from food will vary according to locality and season. In some places and among some races the proportion of uncooked food used is much greater than in other places and among other races. In general, in summer and in autumn the quantity of fruit and food ingested in the raw state is greater than at other seasons, and during the summer and autumn there is also greater danger from the transportation of disease germs from the ground in the form of dust and the amount of liquids imbibed is greater. The elements of predisposition according to place and time upon which epidemiologists are so fond of laying stress are not, therefore, absent from the source of infection now under consideration.

I have thus far spoken only of the secondary infection of food by pathogenic microörganisms, but, as is well known, the substances used for food may be primarily infected.

Chief in importance in this latter category are the vari-

ous entozoa and other parasites which infest animals slaughtered for food. The dangers to mankind resulting from the diseases of animals form a separate theme which would require more time and space than this address affords for their proper consideration. I shall content myself on this occasion with only a brief reference to infection from the milk and flesh of tuberculous cattle.

It has been abundantly demonstrated by numerous experiments that the milk from tuberculous cows is capable, when ingested, of causing tuberculosis. The milk may be infectious not only in cases in which the udder is tuberculous but also when the tuberculous process is localized elsewhere. How serious is the danger may be seen from the statistics of Bollinger, who found with cows affected with extensive tuberculosis the milk infectious in eighty per cent. of the cases, in cows with moderate tuberculosis the milk infectious in sixty-six per cent. of the cases, and in cows with slight tuberculosis the milk infectious in thirty-three per cent. of the cases. Dilution of the infected milk with other milk or with water diminished or in sufficient degree it removed the dangers of infection. There is reason to believe that many of the so-called scrofulous affections in children are due to infection from milk derived from tuberculous cows. Probably for adults the danger of acquiring tuberculosis from the use of infected milk is relatively small. Bollinger estimates that at least five per cent. of the cows are tuberculous. From statistics furnished me by Mr. A. W. Clement, V. S., it appears that the number of tuberculous cows in Baltimore which are slaughtered is not less than three to four per cent. Among some breeds of cows tuberculosis is known to be much more prevalent than this.

There is no evidence that the meat of tuberculous cattle contains tubercle bacilli in sufficient number to convey infection, unless it be very exceptionally. Nevertheless, one will not willingly consume meat from an animal known to be tuberculous. This instinctive repugnance, as well as the possibility of post-mortem infection of the meat in dressing the animal seem good grounds for discarding such meat. The question, however, as to the rejection of meat of tuberculous animals has important economic bearings and has not been satisfactorily settled. As to the propriety of the rejection of the milk from such animals, a matter, however, not easily controlled, there can be no difference of opinion.

The practical measures to adopt in order to avoid infection from the food are for the most part sufficiently obvious. Still it is not to be expected that every possibility of infection from this source will be avoided. The pleasure of living would be destroyed if one had his mind constantly upon escaping possible dangers of infection. It is difficult to discuss the matters considered in this address without seeming to pose as an alarmist. But it is the superficial and half knowledge of these subjects which is most likely to exaggerate the dangers and awaken unreasonable fears. While one will not, under ordinary circumstances, refrain from eating raw fruit or food which is palatable, although it may not have been thoroughly sterilized by heat, or from using the natural water unboiled, in the fear that he may swallow typhoid or cholera bacteria, still in a locality infected with typhoid fever or cholera he will, if wise, not allow himself the same freedom in these respects. Cow's milk, unless its source can be carefully controlled, when used as an habitual article of diet, as with infants, should be boiled or the mixed milk of a number of cows should be selected; but this latter precaution offers less protection than the former.

In most places in this country we are sadly lacking in good sanitary inspection of the food, especially of the animal food, offered for sale. One cannot visit the admirable slaughter-house in Berlin or that in Munich, and doubtless similar ones are to be found elsewhere, and watch the intelligent and skilled inspection of the slaughtered animals without being impressed with our deficiency in this respect. In large cities an essential condition for the efficient sanitary inspection of animal food is that there should be only a few places, and preferably only one place, where animals are permitted to be slaughtered. Well-trained veterinarians should be selected for much of the work of inspection.

It may reasonably be asked that the National Government, which has already spent so much money for the extermination of such diseases as pleuro-pneumonia of cattle and hog cholera, which are not known to endanger the health of mankind, should turn some of its resources and energies also to means for the eradication of tuberculosis from cattle, which is a scourge not only to the economic interests of farmers and dairymen, but also to the health of human beings.

Without any pretension to having done more in this address than to sketch here and there a few principles derived from bacteriological researches concerning only some of the most widely distributed external sources of infection, I trust that enough has been said to show the folly of any exclusive dogma as to modes of infection. The ways of infection, even in one and the same disease, are manifold and various, and can never be resolved into exclusive hypotheses, such as the drinking-water hypothesis, the ground hypothesis, etc.

It follows, therefore, that it is not by sanitary improvements in one direction only that we can control the spread of preventable epidemic diseases. In one situation improvements in the supply of drinking-water check the prevalence of typhoid fever, in another place similar measures show no such influence; or again, in one city the introduction of a good system of sewerage diminishes epidemic diseases, and in another no similar result follows. We should, therefore, aim to secure as far as possible good sanitary arrangements in all directions and in all respects.

It has also been rendered evident in what has been said that infectious agents differ markedly from each other in their behavior, so that while public sanitation aims at those measures which are found to be most widely beneficial, it should not forget that each infectious disease is as much a separate problem in its prophylaxis, as in its symptomatology, etiology, and treatment. It will not aim to combat cholera with the means found best suited to scarlet fever, but it will adapt preventive measures as directly to the specific end in view as possible.

In presenting to you the results of researches, chiefly bacteriological, concerning the scientific basis of preventive medicine, I hope to escape the accusation of one-sidedness and narrowness by the statement that I do not for a moment intend to imply that the bacteriological method is our only source of accurate knowledge on the subjects which have been considered. My aim is accom-

plished if I have succeeded in making clear that this method has established facts which aid in a clearer conception of the causes of some important infectious diseases, in a better understanding of the sources and dangers of infection, and in a more efficient selection and application of sanitary measures.

If this science of only a few years' growth has furnished already acquisitions to knowledge so important, so far-reaching, may we not look forward with assurance to the solution of many dark problems in the domain of infectious diseases, problems the solution of which may yield to preventive medicine a future of usefulness and success which we cannot now foresee.

ORIGINAL ARTICLES.

TETANOID PARAPLEGIA, WITH CASES.

By JAMES K. YOUNG, M.D.,
INSTRUCTOR IN ORTHOPEDIC SURGERY, UNIVERSITY OF PENNSYLVANIA, AND ATTENDING ORTHOPEDIC SURGEON, OUT-PATIENT DEPARTMENT UNIVERSITY HOSPITAL.

Since attention was first directed in 1873, by Seguin,[1] to a symptom group now known as tetanoid paraplegia (Seguin), spastic spinal paralysis (Erb[2]), and tabes dorsal spasmodique (Charcot[3]), etc., much has been written upon the subject. Some confusion, however, still exists, owing in great measure to the multiplicity of terms by which the affection is known. In fact, many of the statements made in the first paper of Seguin were subsequently modified; out of the five cases reported, three were cases of Pott's disease, one was a case of amyotrophic lateral sclerosis (verified by post-mortem examination), and one a case of specific myelitis.

From these severe cases with marked lesions, to those functional cases dependent on genital or other peripheral irritation (Sayre), the number and variety of cases presenting a tetanoid condition of the muscles is large. These, from a pathological standpoint, are best divided, according to Seguin, into those due to

1. Primary sclerosis of the lateral columns (crossed pyramidal column);
2. Various lesions of the spinal cord, chiefly myelitis;
3. Functional tetanoid paraplegia (Sayre); and
4. Defective cerebral development.

It is, however, more particularly with that group of the affection occurring in children (frequently premature), in which, with or without defective cerebral development, with or without a discoverable lesion, the limbs are contracted, adducted, stiffened, and incoördinate, that the writer is interested, and of which he wishes to record five cases which have come under his notice during the last three years. These cases are such as that referred to by Seguin,[1] of a child, six years of age, attending his clinic, and of the two boys reported by Erb,[2] aged four and a half and three and a half years respectively, the first of premature (seven months) birth, in none of which was there any hereditary predisposition or cause discoverable. Similar cases were also recorded, before the disease was well understood, by such orthopedic writers as Adams,[3] who described them as "deformity with rigid muscles," and also earlier by Little,[4] as "spastic contraction," and it is interesting to observe that both refer to premature birth as a probable cause, the latter[5] citing twelve cases out of twenty-four, eight of whom were in the seventh month, as were also one of Erb's and one of the writer's.

Symptoms.—In children the condition usually appears at birth, or within the first year, although it may occur later. There is no osseous lesion (Pott's) nor pressure symptoms (myelitis), and they present the following symptoms: The lower limbs are drawn by the strongest muscles into a condition of spasmodic rigidity, the thighs flexed upon the pelvis and slightly adducted, the knees flexed and firmly adducted, so that they touch, or even overlap, the feet inverted and strongly extended in a position of extreme equino-varus. The contractions readily yield to firm, continuous manual pressure, but immediately return upon its removal. The child stands with assistance, resting upon the ball of the foot and toes, and walks, if at all, with a rapid, swinging, irregular gait, typical of the disease, and with the knees overlapping at every step. There is usually no anæsthesia, ataxia, atrophy, or any vesical or rectal incontinence, such as is found in the graver forms. There is no loss of equilibrium standing with the eyes closed, and the reflexes are exaggerated.

In the upper extremity the same condition exists, but to a less degree. The arms are approximated to the side, the forearm slightly flexed, and the hands flexed and pronated. The flexors of the trunk are sometimes contracted, and the head may be drawn forward and to one side (wry-neck). Strabismus may occur early, and occasionally persists. The configuration of the head at times resembles that of the idiot, and with the half-silly, vacant stare, and an imperfect speech, presents the appearance of a lack of intelligence which does not always exist.

Case I. was studied by the writer while under the care of Dr. Roberts at the Philadelphia Hospital, and the report is taken from his Clinical Lectures:[6]

[6] Clin. Lectures on Orthopedic Surgery, No. 1, 1886, p. 10.

"Barney, æt. six years. No record or information could be obtained regarding previous history. . . . The thighs are adducted and slightly flexed upon the pelvis. The legs are held firmly at a moderate degree of flexion at the knee-joint. The feet are extended and inverted in the position of pronounced equino-varus. All muscular groups of the lower limbs are in a condition of spasmodic rigidity. . . . These contractions may be temporarily overcome by firm and continuous pressure, but immediately reappear upon the removal of the opposing force. Locomotion, with assistance, is accomplished with difficulty by a swinging, discordant gait typical of the disease, the patient walking only upon the ball of the feet and toes, the weight of his body not being sufficient to overcome the contraction and bring the heels to the floor. The other symptoms characteristic of the central lesion—deficient intelligence, strabismus, exaggerated muscular reflexes, and general rigidity and spasm of the muscular system—are all present. Tenotomy of each tendo Achillis was performed, with marked improvement in his condition."

CASE II.—Ella S , female, æt. two years, residing in Philadelphia, came under my care in September, 1886. Father blacksmith by occupation, in good health, but all his family had died of phthisis. Mother in good health, but natural sister has chorea. The child has one brother and three sisters, all in good health, except one sister who has urinary trouble (?).

There was no direct cause for the deformity. It was first noticed that the child could not sit alone nor creep, and later, that it could rise but could not stand nor walk alone. The lower extremities were in a condition of spastic contracture, the feet being in a position of equino-varus.

Under tonics, sedatives, and massage without tenotomy, the condition rapidly improved, and the case was reported by letter after four months cured.

CASE III.—Eddie S., male, æt. five years, born in Pennsylvania, came under the writer's care in the spring of 1887. Father, laborer, was in good health. The mother has some uterine disease (?). No hereditary tendency could be elicited, nor cause assigned for the deformity. It was first noticed that the child walked late (not until two and a half years). The symptoms of contracture gradually advanced, and an examination presented the condition above described. The patient was put under treatment, but disappeared from notice before a cure had been effected.

CASE IV.—Annie D., æt. five years, born in Ireland, of Irish parents. Father, laborer, in good health. Mother in fair health. Has two brothers and one sister, all in good health. There is no hereditary predisposition or cause known.

It was first noticed when the child began to walk, that the left ankle was weak. The patient is a well-nourished brunette child in good general health. The left lower extremity is somewhat wasted, and in the position already described, the foot in a position of equino-varus, its flexion and extension (extreme) limited by spasmodic contraction. The temperature is somewhat lowered. Under appropriate treatment the case improved.

CASE V.—Maggie F., female, æt. four, born in New Jersey, of healthy Irish parents, at the seventh month, the mother having suffered a severe fall. She was hand-fed from birth, and for many months she remained small and delicate. There was no hereditary predisposition to nervous affections, nor any cause known. Her present condition (May, 1889) is that of a small, brunette, poorly developed child, with "silly" expression and hesitating speech. The mental condition, however, appears to be good. There is no vesical or rectal difficulty. The skin and muscles are normal. Both lower extremities, and the right upper extremity, are in a condition of tetanoid paraplegia. The position of the former is characteristic, and the contractions can all be overcome by manual pressure except the left foot, which cannot be brought beyond 90°. With assistance, locomotion is accomplished by short, quick, irregular steps, the knees crossing and the feet extended. She is still under observation and treatment.

Prognosis will depend upon the cause. If this be a central lesion, little can be accomplished without operative interference; but if from peripheral irritation, the removal of this may at least temporarily relieve the symptoms.

Treatment should consist of tonics and sedatives combined with friction and massage. If the contraction appears to be due to an adherent or contracted prepuce, circumcision should be at once performed. This, in a certain number of cases, has no effect whatever, or is only temporarily beneficial, as pointed out by Dr. Eugene Dupuy,[1] referring to the cases reported by Sayre,[2] and the writer has observed the same in a case operated upon by another surgeon.

An attempt should be made to straighten the contracted parts by mechanical stretching, after the well-known method of Dr. Newton M. Schaffer, of New York, failing in which tenotomy should be performed, the parts that will require division being usually the tendo Achillis, adductors of foot, hamstrings, and adductors of thigh. This, as the researches of Rupprecht[3] demonstrate, not only improves the position of the limbs, but also decidedly benefits the mental condition. After tenotomy an ordinary varus walking shoe, combined with a Congdon to fix the knee, should be worn for some time.

A THIRD CASE OF HEREDITARY CHOREA.[4]

BY CLARENCE KING, M.D.,
OF MACHIAS, N. Y.,
PHYSICIAN TO THE CATTARAUGUS COUNTY INSANE ASYLUM.

THE earliest mention of the hereditary form of chorea which we find in medical literature is in a communication from Dr. C. O. Waters, of Franklin, N. Y., to Prof. Robley Dunglison, of Philadelphia,

[1] Journ. Nerv. and Ment. Dis., April, 1887, p. 232.
[2] On Reflex, Paralysis, etc., Trans. Amer. Med. Assoc., 1870.
[3] Volkmann's Clinical Lectures.
[4] A paper read before the Cattaraugus County Medical Society, June 5, 1889.

and is dated May 5, 1841. The salient points differentiating it from the ordinary form of the disease were stated by him to be: 1st, its development in adult life; 2d, heredity its only known etiological factor; 3d, its constantly progressive character and death its only termination. This letter was published by Prof. Dunglison in his forthcoming work on the Practice of Medicine, and may be found in the third edition, volume 2, page 216.

In 1872 Dr. George Huntington, of Pomeroy, Ohio, called attention[1] to this disease, and until recently I have considered this the second paper published on the subject. But, from a valuable monograph by Dr. Wharton Sinkler, of Philadelphia, a reprint of which he has kindly sent me, I find that Dr. Irving W. Lyon preceded Huntington with a paper[2] which was published in the *American Medical Times* for December 19, 1863. He speaks in particular of the hereditary nature of the disease, and cites brief histories of three cases in his practice.

I have been familiar with this form of chorea for years, and recollect the fear and timidity which possessed me when in childhood I was obliged to pass one of these patients on my way to and from school. Later, I made this disease the subject of a thesis which I presented for my degree in medicine in February, 1885, and which was published in the *New York Medical Journal* of April 25th. In that brochure I narrated the history of the disease as observed in these patients, and made reference to the observations of Waters and Huntington.

A second case of hereditary chorea occurred in my practice at the Cattaraugus County Insane Asylum in 1886, and a short account of it was given by me in the *Medical Press of Western New York* for December. I now wish to call attention to a third series of cases, two of the patients likewise being under my care at the insane asylum.

Mrs. S., aged thirty-eight, married, mother of one child, which died in infancy. Has suffered from chorea since she was twenty years of age; was admitted to the asylum May 19, 1886, and placed in the ward for imbeciles. She died of chorea January 30, 1888.

The earliest occurrence of this disease which we can find among this patient's ancestors was in the person of her paternal grandmother, Mrs. C. She is said to have died with chorea at an advanced age, having suffered with it for many years.

Mrs. C. had four children, one of whom—Abel C., the father of our patient—was afflicted with it from about the age of forty to the time of his death at seventy years; the other three children escaped, and none of their progeny, so far as is known, have ever developed the disease. Abel C. was an inmate in the poor department of our county asylum for about two and a half years, and died there several years before my service as physician began. No written history of his case was made, but the superintendent and my father, who was the physician in attendance at that time, remember well the patient.

Abel C. had six children, all of whom lived to have families. Two of these, Mrs. S., our patient at the time of her death, and Henry C., who is now under our care, became afflicted with the disease, the other four children escaping it. Of their descendants, however, no reliable information is obtainable.

Henry C., Mrs. S.'s brother and our present patient, is sixty years of age and has had this disease gradually coming on for fourteen years. He is the father of eight children, the eldest about twenty-two years of age. He has two children under fourteen years of age. Two of his children are said to show unmistakable signs of the disease, their ages being eighteen and sixteen years.

Present condition.—Nearly every muscle seems to be involved, the movements being increased if the patient is watched, but ceasing entirely during sleep. Respiration irregular; can walk without assistance but occasionally falls; is able to stand for a short time and walk a few steps with his eyes closed;[1] patellar reflex present; appetite good but not voracious; body well nourished; bowels regular; somewhat wakeful at night; eyes apparently normal; memory poor and mind evidently failing, but without hallucinations.

Elsewhere[2] I have made the statement that the appetite is greatly increased, especially in the advanced stages of the disease, and continues unabated until a short time before death. This I have noticed in two of my patients, and it is said to have been the case with others in the family of my first patients, at least, who died of the disease. Mrs. S. had food in her mouth almost continually, but it would be impossible to estimate how much she swallowed, as a large proportion of it escaped from her mouth during mastication. Henry C.'s appetite is only good for a non-laboring man. Other writers on hereditary chorea make no mention of an excessive appetite attending the disease, but several speak of the "good appetite" which their patients enjoy.

I have also noticed that some patients have certain peculiarities about their movements which others have not. Thus, Mrs. S. was accustomed to stand for many hours, especially when trying to masticate food, with her body thrown forward to the level of her hips and her arms extended backward by the side of her body, the palms being upward. She only assumed the upright position, unless spoken to,

[2] Chronic Hereditary Chorea. By Irving W. Lyon, M.D.

[1] Other patients, not as far advanced with this disease, whom I have tested for this symptom, so prominent in locomotor ataxia, have been able to stand for any length of time and walk any distance with the eyes closed.

[2] Medical Press of Western New York, December, 1886.

at long intervals and then only for a few seconds. Henry C. frequently extends one arm as if to grasp some object in front of his face. Another patient developed a peculiar gait in walking which I have described in detail in a former paper.

It has been said that this form of chorea appears only in adult life, but to this rule there are exceptions. Hoffmann has reported a case in which choreic movements began at ten years, and Lyon one in which they had existed "from puberty." As mentioned above, two of Henry C.'s children showed choreic symptoms at sixteen and eighteen years of age.

In the earlier stages the sexual function seems to be but little impaired; later, it is notably weakened or entirely lost. Henry C. became the father of two children after he began to show choreic symptoms. Mrs. S. did not menstruate while under our observation. Other writers have made no observations as to the sexual functions, and I am unable to find another instance mentioned in the literature of the disease where a child was born after either parent became choreic. Huber mentions a lady, a sister of his patient, who gave birth to a child in 1877, having been "slower in her work, and indifferent" since 1873. After this she became "unruly and forgetful," and in 1880 showed choreic movements of the elbow.

Concerning the pathology of the disease, I will admit that I know nothing definite. In the case of the father of Huber's patient, who died insane, having had chorea for years, an autopsy revealed the presence of "pachymeningitis and internal meningitis." Dr. William Osler, of Philadelphia, has recently made an autopsy on a patient dying with this disease, but I have not seen a report of it as yet. One fact, however, appears to be demonstrated to the satisfaction of the profession, and that is, the close relation between hereditary chorea and other diseases of the nervous centres, notably epilepsy and insanity. Indeed, insanity appears to be a quite common termination of the disease, and in a number of instances epilepsy has been found in patients who, from their hereditary predisposition, we might expect to have chorea. My father, who was acquainted with choreic families on Eastern Long Island, possibly the same that Huntington observed, states that hereditary insanity was common there, and that certain individuals in choreic families became insane without having chorea.[1]

The treatment of this disease therapeutically is as unsatisfactory as our knowledge of its pathology. Hygienic measures and systematic training may postpone or prevent its development in a person predisposed to it, but after it has once made its appearance its march is constantly forward, and nothing can stop its progress but death. Sinkler prescribed large doses of hyoscine and arsenic, and thinks for a time the movements were less severe, but admits "there was no material benefit done." In the treatment of my patients I have not attempted to cure or ameliorate the twitching of the muscles. I rest content in remedying, so far as I am able, any intercurrent malady or functional irregularity which may be present, and leave the unfortunate being to await his final cure from more skilful hands than mine.[1]

MEDICAL PROGRESS.

Rapid Cure of Erysipelas.—In the discussion which followed the reading of a paper on "The Use and Misuse of Disinfectants and Deodorizers in Medicine," by Dr.

[1] My father's native town of East Hampton, Long Island, was settled as early as 1649, and choreic families have lived there for generations. Previous to 1800 there were several emigrations from the town to eastern and northern locations, one of these being to the western shores of Lake Champlain, near Plattsburg; another to the Mohawk Valley in Oneida County; another to Delaware County; and a fourth one to some place in Vermont. It is interesting to note that Dr. Waters's observations were made upon patients living at Franklin, Delaware County; two of the three cases given by Lyon were in "New York State," town and county not given; Huntington's cases were on "Eastern Long Island;" and Sinkler's first patient was "born in New York State." The father of my second patient came from Vermont, town unknown, and the parents of my present patient came from Oneida County, New York. One of Lyon's cases was in Connecticut, only a short distance by water from Long Island, and Sinkler's second case was in Wyoming County, Pa., only seventy-five miles from Delaware County, N. Y. My first choreic patients were of Welsh descent, the great grandfather (who afterward had the disease) coming from Wales and settling in Vermont. He afterward moved to Plattsburg, N. Y., and still later came to Western New York. All the other cases reported have been in Europe. Possibly, if we were in possession of the complete ancestral history of our patients, we could trace all the cases of the disease in this country, except my first case, to one centre of origin at East Hampton, Long Island. Or is this coincidence merely accidental?

Sée has also written on the subject, but I cannot give reference to his paper.

Abstracts from the papers of Ewald, Huber, Zacher, and Hoffmann have been published in the American Journal of the Medical Sciences.

Henry Jackson, in the Suffolk District Medical Society, DR. J. C. WHITE took exception to the reader's statement regarding our lack of control over erysipelas. He said:

"I would like to state that I consider that one may get absolute control over erysipelas generally within three days by simple treatment. Of one hundred cases of ordinary facial erysipelas treated I should not expect more than three that would not yield within three days, very likely within forty-eight hours with the simplest antiseptic treatment. My custom is always to treat cases of that sort by the application during alternate hours of the day and evening of a mild solution of carbolic acid in alcohol and water as an evaporating lotion. It is only in very exceptional cases that the disease is not almost completely under control, and has disappeared within forty-eight hours; but after three days it would be extraordinary if by this means every vestige of the disease had not disappeared. This has been my only treatment in erysipelas for many years. I have never known it to fail. I have never given a drop of medicine internally. I feel that I have absolute control over the disease. I am speaking now of ordinary erysipelas, not of the deep-seated phlegmonous erysipelas, of course."

When asked the strength of the solution used, Dr. White gave the following formula:

R.—Cryst. carbolic acid . . . ʒss.
Alcohol }
Water } . . . . āā ʒjv.—M.

—*Boston Medical and Surgical Journal*, June 13, 1889.

Peculiar Nervous Affection of the Upper Limbs.—In the *Nouvelle Iconographie de la Salpêtrière* just issued, M. PAUL BLOCQ describes an affection which is characterized by symmetrical atrophic paralysis, with disorder of sensation exactly corresponding to the musculo-cutaneous distribution of the ulnar nerve. In these characters the affection resembles amyotrophy of cord and nerve origin and primary myopathy, as well as amyotropic lateral sclerosis. It is an affection which runs parallel with a similar lead neuritis of the musculo-spiral nerve. What, then, constitutes its peculiarity? That there exists a group of such cases, having no very obvious cause, is, perhaps, sufficient to warrant a separate clinical class being established. Cases of the kind have followed typhoid fever, and very likely have been due to neuritis. Eleven years ago, in the *Archives Générales de Médecine*, M. Panas recorded a case of ulnar paralysis in one nerve supervening twelve years and a half after a fracture of the elbow on the same side. In the groove at the inner side of the elbow the ulnar nerve developed a fusiform swelling which led to the formation of a typical "main en griffe," interosseal atrophy, and disturbed sensations, with diminished tactile sensibility in the ulnar distribution. The symmetry of the peculiar affection described by Blocq is an additional feature of the disease, and, though it recalls diseases due to lesions about the lowest part of the brachial enlargement of the cord, still this symmetry alone cannot be taken as evidence of the situation of the lesion. For example, lead was long thought to exercise a special primary influence over the motor nerve-cells of the anterior cornua of the spinal cord, until it was proved that it had a great affinity for the distal extremities of these cornual cells, producing a peripheral neuritis rather than a myelitis.—*Lancet*, June 8, 1889.

Treatment of Amenorrhœa.—DR. NISALO, in the *Gazette de Gynécologie* for June, 1889, gives the following formulæ for the treatment of amenorrhœa:

R.—Decoction of barley . . ʒxiij.
Mucilage . . . . ʒv.
Water of ammonia . . gtt. xl.—M.

The above is for vaginal injection, and should be used four times daily, simultaneously the following should be given internally in three doses.

R.—Absinth water . . . ʒjv.
Syrup of saffron . . . ʒj.
Orange-flower water . . ʒss.
Castor oil }
Savine oil } . . . āā gtt. ij.—M.

Treatment of Senile Pruritus with Salicylic Preparations.—PROF. BESNIER, of Paris, advises the following treatment for senile pruritus: The entire body should be washed every evening with a quart of warm water, to which about two drachms of the following solution have been added:

R.—Carbolic acid . . . . . ʒj.
Aromatic vinegar . . . . fʒvij.—M.

Then either of the powders given below should be dusted over the body:

Salicylate of bismuth . . . ʒv.
Starch . . . . . ʒiij.—M.

or,

R.—Powdered salicylic acid . . . ʒiij.
Starch . . . . . ʒiij.—M.

Antipyrin in Diabetes.—At the last meeting of the Académie de Médecine of Paris, reported in part in the *Wiener klinische Wochenschrift*, May 30, 1889, DR. PANAS spoke of the beneficial results which he had observed to follow the use of antipyrin in diabetes. In several cases there was a complete disappearance of sugar from the urine after five or six days' treatment. Panas concludes that daily doses of forty-eight grains of antipyrin promptly check the formation of sugar.

Some authorities are of the opinion that the effects of antipyrin is only temporary. GERMAIN SÉE says that out of eighteen cases of diabetes in which he has tried the drug, he considers it most efficient in all cases in which there is no cachexia or tuberculosis and in which the quantity of sugar in the urine does not exceed two and a half or three ounces to the quart. Besides its action in reducing the quantity of sugar, it also relieves both the nervous and skin affections attending the disease. It has no beneficial effect upon albuminuria.

DR. A. ROBIN, of Paris, asserts that the use of antipyrin does away with the necessity for strict dietary measures. In cases in which it does not cause a rapid decrease in the quantity of sugar, Robin discontinues its use. He not only measures the daily percentage of sugar, but also the quantity and specific gravity of the urine. If the quantity decreases and the specific gravity remains stationary, he continues the use of the drug. In cases, however, in which its use causes a decrease in the quantity and an increase in the specific gravity, he considers its use most inadvisable. Albuminuria need not

be regarded as a contraindication for its use, although additional caution is advisable. If symptoms of weakness, loss of flesh, loss of appetite, pallor of face, oppression, etc., manifest themselves, the continuance of the drug will do more harm than good. Robin gives forty-eight grains *pro die* for ten or twelve days, but only thirty-two grains when albuminuria exists. He combines antipyrin with alkalies, preferably with bicarbonate of soda (one part of the latter to two of antipyrin), and gives four doses daily.

DUJARDIN-BEAUMETZ and WORMS both claim that antipyrin in conjunction with quinine, as well as with other antipyretics, speedily lessens the quantity of sugar in the urine of diabetics.

Methacetin, a New Antipyretic.—Methacetin is a derivative of amido-phenol; properly speaking, it is the methyl-ether of amido-phenol. The drug is a flaky powder, of a light-red color, odorless, and has a slight salty bitter taste. It melts at a temperature of 260° F., is soluble in cold water, but more quickly so in warm water, dissolves rapidly in alcohol. When given to animals in small doses it produces a rapid decrease of temperature, and also has a marked effect upon the nervous system. Fatal doses in rabbits were forty-seven grains. The urine contained no hæmoglobin. Experiments upon children show that small doses (three grains to four and a half grains) produce a considerable fall of temperature. Profuse perspiration frequently follows the use of the drug, and in one case collapse has been noted. Other accompanying symptoms have not been observed. The value of this new antipyretic is still undetermined.

Treatment of Chilblains.—The following formulæ, for the treatment of chilblains, are quoted from the *New York Medical Record* of June 8, 1889:

I. ℞.—Chloride meth. . . . ʒij.
Hydrochlorate of cocaine . grs. viij.
Compound camphor liniment ʒiij.
Soap liniment . . . ʒv.—M.

II. ℞.—Belladonna liniment . . ʒij.
Aconite liniment . . . ʒj.
Carbolic acid . . . ♏vj.
Flexile collodion . . . ℥j.—M.

III. ℞.—Castor oil, Flexile collodion, Spirits of turpentine } āā ʒjv.—M.

IV. ℞.—Spirits of camphor, Tincture of opium } āā ʒij.
Carbolic acid . . . grs. xl.
Alcohol . . . . ʒjv.
Water . . . . ʒjv.—M.

Cocaine Injections in Spastic Articulary Contractions.—In primary inflammatory contractions of the joints, in such cases, therefore, where a contraction of the joint has been the immediate result of an inflammatory irritation or an inflammation of such a part, DR. LORENZ, in the *Centralbl. für Chirurgie*, June 8, 1889, strongly advocates the use of cocaine injections at the seat of the contraction. For this purpose Lorenz uses a Pravaz syringe with a long needle and injects a half or even a whole syringeful of a ten per cent. solution of cocaine into the contracted joint. The injection is always immediately followed by a cessation of pain, and in a few minutes the limb may be extended, fixed in proper position, or extension applied. This treatment is particularly useful in the straightening of spastic flatfoot. Children endure cocaine very well; when used in adults great caution is necessary, and very small quantities of the drug will often have the desired effect. The injection should be performed under strict antiseptic precautions. At the Albert Clinic in Vienna, general anæsthesia is now never resorted to in correcting primary inflammatory contractions.

An Epidemic of Chorea.—Last summer, reports DR. LAQUER in the *Centralb. für Gynäkol.*, June 8, 1889, there was an epidemic of chorea in a girls' school in Schadenheim, Germany. The disease started in a girl who, two years previously, had had an attack of chorea minor. The symptoms constituted clonic muscular twitchings of the face, trembling of the arms, and hemiparesis of both upper and lower extremities. The epidemic lasted for over a year and a half; in all, sixteen children were affected; Laquer ascribes the symptoms of chorea manifested to an hysteric origin.

An Emmenagogue Pill.—The following emmenagogue pill is recommended by *L'Union Médicale*, June 6, 1889:

℞.—Powdered valerian, Powdered saffron } āā grs. xxxj.
Black oxide of iron . . ʒj.
Syrup of absinth and powdered gum . . . . . q. s.

Make into forty pills. At first one pill should be taken at every meal; later, the dose may be increased to two pills. The prescription is specially valuable in establishing normal catamenia in young chlorotic subjects.

The Mechanical Treatment of Erysipelas.—It is only fair to the profession that, when a new therapeutic method is being recommended, the author should take equal pains to record all cases in which his treatment has failed as well as those in which it has proved successful. With this honest end in view, DR. ANTON WÖLFLER, in the *Wiener klin. Wochenschr.* of June 6, 1889, after describing his method of treating erysipelas, starts out with reporting two cases in which the treatment was unsuccessful, but follows with the report of three successful cases.

Dr. Wölfler's mode of treatment is to outline the area of the disease with strips of sticking-plaster, and he has found that the disease will not overreach these limits. In a case of erysipelas following an ulcer of the arm, strips of plaster were placed about the wrist, and, as the subaxillary glands seemed already affected, the second strip was placed over the shoulder and along the sides of the thorax, and the limits were completed by a third strip at the waist. The disease progressed, accompanied with fever, until it had reached the sticking-plaster, but went no further, the fever ceased, and rapid healing followed. Another case recorded was that of erysipelas following a leg ulcer. Two bands of adhesive plaster were placed around the thigh. The disease quickly extended to the first band, and a very slight inflammation extended beyond it, but did not reach the second band.

So soon as the course of the disease was checked, fever disappeared and rapid healing followed. The third case was one of facial erysipelas. A strip of plaster around the neck quickly checked the progress of the disease, and cure followed. Of the two unsuccessful cases, the first was one of gangrenous erysipelas of the thigh and pelvis, and the patient was in a dying condition when brought under treatment. Death occurred in twenty-four hours. The second was a case of erysipelas of the chest following an operation for empyema, although the disease did not go beyond the limits of the plaster strips, yet the patient was so enfeebled death occurred three days after the commencement of the treatment. In the number of the above mentioned journal for June 14th, Wölfler reports seven additional cases, all of which resulted favorably. Three cases were erysipelas of the extremities and four were facial erysipelas, the latter being controlled by plaster bands around the neck.

A new Formula for the Administration of Cod-liver Oil.—The *Lyon Médical* gives a new method of administering this drug. Equal parts of the oil and lime-water are mixed, and a milky liquid is obtained, which has no odor and is of the consistency of syrup. It can be flavored if desired with a little essence of citron or vanilla. The oil, thus saponified, is most pleasant to take, does not adhere to the walls of the buccal cavity, and leaves no disagreeable after-taste. It can be given in cases with the most delicate stomach. The mixture keeps well.

A Case of Death following Suspension.—In the *Lyon Médical*, No. 20, we read of the following case of death following suspension, reported by DR. GORECKI. The patient was a man, aged forty, who for five years previously had been suffering from tabes, and who, after reading of the excellent results obtained by suspension, bought an apparatus. The disease had taken a very rapid course in him, paraplegia being almost complete. He was suspended two or three times daily by his man servant. The first seven suspensions were followed by most marked improvement, and the patient was able to walk a few steps. After the eighth suspension he suddenly lost the power of speech and hearing, his sight, however, being unaltered and no paralysis existing. Although active treatment was immediately resorted to, swallowing soon became impossible, sight was lost, and general paralysis quickly set in. The symptoms became more and more aggravated, and in twenty-four hours the patient was dead; the immediate cause of death being asphyxia.

Preventive Treatment of Megrim.—DR. HAMMERSCHLAG, says the *Weiner med. Presse*, June 2, has used the following formula in warding off attacks of megrim with great advantage. So far, it has not failed him in a single instance:

℞.—Citrate of caffeine . . . grs. xv.
Phenacetin . . . . grs. xxxj.
White sugar . . . . grs. xv.—M.

Make into ten powders in capsules. Sig. One capsule to be taken between the attacks.

Phenacetin alone is not so efficacious. The treatment may be continned until the attacks cease, which, however, will not be long.

Post-partum Irrigation with Hot Water.—The question of post-partum irrigation is one which has of late been widely discussed, but has by no means been definitely settled. Whilst, on the one hand, the majority of practitioners are in favor of this procedure, yet there are a vast number that maintain that it is valueless, and are especially opposed to the use of corrosive sublimate or carbolic solutions, this on account of their toxic properties. It has, however, been definitely proved that the lochia of healthy lying-in women does not contain either streptococci or other pyogenic bacteria. With this point in view, DR. DEIPSER, in the *Centr. für Gyn.*, June 1, 1889, strongly recommends the use of simple hot water douches. He claims that the temperature of the water which he uses is not conducive to the growth of germs, and even if all are not killed, the stream will wash them away, together with the blood-clots. Deipser lays particular stress upon the hemostatic properties of hot water. Nothing, he says, causes a more rapid contraction of the uterus. His method is to raise the back slightly, so as to facilitate the running off of the liquid, and the douche used is of a temperature of 122° F. As this heat will be unpleasant to the external organs, although well borne by the internal ones, Deipser suggests that the former be covered with a small quantity of vaseline. The quantity of the douche should be about one quart, and it should be undertaken as soon as the placenta has come away, and while the cervix is still open.

Eschscholtzia California.—The Eschscholtzia California is a shrub-like plant indigenous to North America and especially to California, where numerous varieties are found. A resinous, dark-green extract is obtained from the plant, which is entirely soluble in alcohol, soluble to a great extent in water, slightly so in glycerine, but insoluble in either chloroform or ether. The watery extract is of a red-brownish color and is soluble in water, alcohol, and glycerine, but not in ether or chloroform. BARDET and ADRIAN succeeded in isolating a base from the plant which they take to be morphia; an alkaloid was also obtainable in large quantities. The alcoholic extract was experimented with upon animals, and also tested in thirteen cases, and it proved itself to be a valuable and safe hypnotic and analgetic. The doses given varied from forty minims to two and a half fluidrachms. The following formulæ were found most agreeable:

I.

℞.—Alcoholic extract of eschscholtzia ♏xxx to ʒijss.
Rum
Simple syrup } . . . āā ʒj.—M.

II.

℞.—Alcoholic extract of eschscholtzia ʒvss.
Powdered liquorice root . . q. s.—M.

Make into forty pills. Sig. Five to ten pills daily.—*Deutsche med. Wochenschr.*, May 30, 1889.

Treatment of Habitual Constipation with Electricity.—DR. HAMMOND, says the *Revue de Thér. Médico-Chir.* of June 1, 1889, has successfully treated forty-one cases of habitual constipation with a galvanic current. The negative pole is placed in the anus, and the positive pole applied to the abdomen. Faradization was found useful in promoting a healthy tone of the muscles of the abdomen. In connection with the treatment, saline aperients should be administered.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

EXTERNAL SOURCES OF INFECTION IN RELATION TO PREVENTIVE MEDICINE.

IT is the grand object of preventive medicine to investigate the conditions out of which diseases spring, and to endeavor to discover, so far as possible, how far they are removable and how far they are preventable. In this broad field of inquiry the science of bacteriology has yielded most valuable results. Through the exact methods of investigation which have been applied to the discovery of external morbific agents we are in possession of knowledge of the greatest advantage in forming a clearer conception of the causes of important infectious diseases, which knowledge is indispensable in selecting and applying the measures of prevention. Exactly what is the present state of our knowledge with respect to the external sources of infection in their bearing on preventive medicine is a question for profitable consideration. The profession is indebted to DR. WELCH for the able manner in which he has traversed this question in his Address in State Medicine, delivered before the American Medical Association at its recent meeting at Newport, and printed in this issue of THE NEWS.

It is not the purpose of Dr. Welch to enter into an elaborate discussion of the etiology of individual infectious diseases, but rather to consider "what *rôle*, in harboring and transporting infectious agents, may be played by those substances or media with which we necessarily come into intimate contact, such as the air, the ground, the water, and our food."

The air is a common medium for the transportation of infectious agents, but the danger from this source has been overestimated. Unlike the soil, the air does not form a resting or breeding-place for bacteria. Bacteria may adhere to particles of dust, but they do not exist to any great extent in the air in single detached particles. The air bacteria are derived from the ground, and in order to be taken up by the air they must first become dry. This fact is of great significance in the application of measures for the prevention of infection through this channel. The indications which it suggests are the necessity of guarding against the desiccation, when exposed to the air, of substances which contain infectious germs not destroyed by drying and free ventilation.

A most important source of external infection is the ground. Unlike the air, the ground is the resting or breeding-place of numerous forms of microorganisms, some of which are pathogenic. It is in the superficial layers of the soil that bacteria flourish. Among the pathogenic microörganisms which find their habitat in the ground, are the bacilli of malignant œdema and of tetanus. In favorable situations the bacillus of typhoid fever, of anthrax, and of cholera, may have their abiding-place there, and, under suitable conditions, multiplication of these germs may take place. The tubercle bacilli may also preserve their vitality in the soil for a long period under specially favorable conditions. The soil, however, is not a favorable breeding-place for most of the infectious bacteria.

Bacteria derived from the soil may be introduced into the body, conveyed on currents of air, only when the surface is dry. They may also be conveyed by means of vegetables, by the intervention of domestic animals, by the medium of flies and other insects, and in various other ways. The most important medium, however, is drinking-water, which becomes charged in various ways with these morbific agents.

In preventing infection, directly or indirectly, from the ground, it is of first importance to prevent the pollution of the soil by infectious substances. One means to this end is the adoption of a perfect system of drainage, whereby substances which favor the existence of infectious germs are kept out of the ground. Another means is thorough cleanliness about habitations. In cities, the proper paving of

the streets, absence of unnecessary disturbance of the soil, cleanliness of streets and spaces, and the laying of dust by sprinkling, are important in preventing infection from the ground and dust.

Another vehicle of infection is water. Bacteria abound in water, and even pathological bacteria may preserve their vitality for a length of time in this medium, if they do not actually multiply. So far as our knowledge goes, drinking-water is not a favorable breeding-place for pathological microörganisms. Still, there is no reason for rejecting the belief that both cholera and typhoid fever are conveyed by this medium. Infection from water is to be prevented by avoiding water suspected of infection. When this is not possible, the suspected water should be boiled. The only means of purification of surface water on a large scale is filtration. Domestic filtration is unsatisfactory, but filtration of the general supply, by means of large sand-filters, furnishes excellent results.

Still another medium of infection is our food. Many articles of food form excellent nutritive media for the growth of pathogenic microörganisms. Infection of food may be derived from deposits of dust, from earth, from water used in its preparation, and from contact in various other forms with infection. Milk is particularly liable to convey infection. There may be produced in it, as well as in other forms of food, by bacteria incapable of multiplying in the body, certain organic alkaloids, the so-called ptomaines, which produce poisoning and render the alimentary membrane more susceptible to infection by morbific organisms.

Articles of food may be primarily infected. For example, the milk from tuberculous cows and the flesh of animals infected with parasites. The measures of prevention are obvious. The cooking of food immediately before its use, the boiling of milk when the supply cannot be carefully controlled, and the application of efficient sanitary inspection of all food supplies, form the basis of preventive measures.

We have very hastily and imperfectly sketched the leading points in Dr. Welch's address, which is a fresh and instructive article, full of practical suggestions, and worthy of careful study.

OWING to a reduction in the appropriations, three of the National quarantine stations on the Atlantic coast, one in the Gulf and two on the Pacific coast, will be closed on the 1st of October. The governmental appropriation amounts to $50,000, and as this amount is insufficient to maintain all the stations now in operation throughout the year, two only will be kept open, namely, the one at San Francisco and one on the Gulf coast.

AT the recent annual meeting of the Rhode Island Medical Society, the following officers were elected for 1889–90:

President.—John W. Mitchell.

Vice-Presidents.—William H. Palmer, Robert F. Noyes.

Recording Secretary.—William R. White.

Corresponding Secretary.—George D. Hersey.

Treasurer.—George L. Collins.

Dr. G. L. Collins, Secretary of the Trustees of the Fiske Prize Fund, read the annual statement of the same.

A prize of $250 had been awarded to Dr. Charles V. Chapin, of Providence, for his essay bearing the motto "Their Poison is like the Poison of Serpents," the subject being "The Rôle of Ptomaines in Infectious Diseases."

For 1890 a prize of $300 is offered for the best essay on either of the following subjects:

1. Pathology, diagnosis, and treatment of intracranial tumors, with original observations.

2. How far can disease be prevented by science and legislation?

3. The surgical treatment of wounds and obstructions of the intestines.

THE *Lancet*, of June 29th, states that the University of Oxford, in recognition of his accomplishments in medical literature, and of important services otherwise rendered, is about to confer upon Dr. J. S. Billings, of the American Army, and now attached to the Surgeon-General's Office, Washington, the honorary degree of D.C.L.

DR. HENRY M. HURD, Superintendent of the State Hospital for the Insane at Pontiac, Michigan, has accepted the position of Superintendent of the Johns Hopkins Hospital at Baltimore.

A CONVICTION, under a new law in New York State prohibiting the selling of cigarettes to children under sixteen years of age, has been obtained. The offender was compelled to pay a fine of fifty dollars. This case may be appealed by the conjoint action of the dealers and manufacturers, but this conviction

will diminish to some extent the pernicious use of tobacco by young persons.

AN atrocious outrage upon a country physician was perpetrated on the night of July 1st, at a village called Pleasant Unity, in Westmoreland County, Pennsylvania. Dr. Lewis T. Smith, a graduate of Jefferson and a practitioner of excellent repute, was beaten and nearly murdered by three masked men, who aroused him at night on a pretence that one of them needed to have a tooth extracted. They gained access to the house in this manner, and proceeded to beat the inmates and to ransack the premises. They found money and valuables to the amount of five hundred dollars, which they took away with them, leaving the physician, to all appearances, dead. Dr. Smith's injuries did not prove fatal, but his condition is even yet most critical. There is some hope, however, that he may recover.

DR. STEPHEN WICKES, one of the oldest and most respected physicians in northern New Jersey, died on the 8th instant at his home in Orange, N. J.

Dr. Wickes was born in Jamaica, L. I., March 17, 1813. He was a descendant of Thomas Wickes of the Massachusetts Colony of 1635, his father being Col. Van Wyck Wickes. Having graduated from Union College in 1831, he became a student of the natural sciences at Rensselaer Polytechnic Institute in 1832, and of medicine at the University of Pennsylvania in 1833–34, and in the latter year was graduated from that institution. In 1835 he practised in New York, thence until 1852 in Troy, and from 1852 until February, 1886, in Orange. He was for twenty years an elder of the First Presbyterian Church.

Dr. Wickes will be best remembered by his literary work, to which he applied himself with great industry after his retirement from active practice. He edited the *Transactions of the Medical Society of New Jersey* from 1860 until 1882; also the old *Transactions* of the Society from 1766 till 1858. He published *Topography of Orange; Water Cure in Orange; Memoirs of Thomas W. Blatchford, M.D., of Troy, N. Y.; Living and Dying, their Physics and Psychics; History of Medicine in New Jersey; Sepulture, its History, Methods, and Requisites*, and *History of the Newark Mountains*.

DR. WILLIAM ELMER, an ex-President of the New Jersey State Medical Society, died at Bridgeton on the 26th of June, after an illness of several months, due to Bright's disease. He was the third of a line of physicians in the Elmer family. His grandfather, Dr. Jonathan Elmer, was also a President of his State Society in the year 1787, and in 1788 a United States Senator. Dr. William Elmer was educated at Princeton College, taking the salutatory oration at graduation. He took his M.D. at the University of Pennsylvania in 1836. After a year or more at Blockley, he settled down at Bridgeton in 1838, and rapidly succeeded in practice. He was a leader in medicine not only, but in charitable, educational, and religious organizations in the southern part of Jersey. In 1860 he was in the presidency of the State Society, and his age at death was nearly seventy-five years.

DR. PHILIP F. BRAKELY, who for forty years was the Secretary of the Medical Society of Warren County, New Jersey, died at his home in Belvidere, at the age of seventy-five years, on the 3d of July. He was a representative man in northern New Jersey, just as Dr. William Elmer, who died six days before him, was a most able standard-bearer in the southern section of the State. They both were graduates of the University of Pennsylvania, Dr. Brakely being of the class of 1842. He was early identified with the American Medical Association, and a permanent member of the State Society. His death has been ascribed to the infirmities of advancing age, culminating in cardiac syncope.

SOCIETY PROCEEDINGS.

AMERICAN MEDICAL ASSOCIATION.

Fortieth Annual Meeting, held at Newport, R. I., June 25, 26, 27, and 28, 1889.

(Specially reported for THE MEDICAL NEWS.)

SECTION OF SURGERY.

WEDNESDAY, JUNE 26, 1889.

DR. C. B. PORTER, of Boston, read a paper on

ECTROVERSION OF THE BLADDER.

He first reviewed the more important forms of ectroversion together with the leading operations that have been proposed for its relief. He then gave a history of several cases and reviewed the statistical history of the various operations. With regard to choice of operation, he thought age and the direction of the cleft were the chief factors. No operation has yet secured retention of urine. The operation is not a serious one. None of his four cases had died. Crudelli's operation promises nothing more than the flap-operation. The flaps must be taken from the middle and lateral portions of the

anterior abdominal wall and must be about a third larger than enough to cover the cleft. They must be so made as to secure free circulation of blood in them. Traction must not be made on them. All hemorrhage must be promptly arrested. If delay occurs in the operation, the field must be carefully covered with hot wet flannel. The operation should be made early and no fear need be entertained of closing the cleft. It has been successfully performed at as late an age as forty years. At the close of his paper he exhibited a case upon which he had operated, giving a complete history of the case and method pursued.

DR. W. T. BRIGGS, of Nashville, then read a paper on

THE CHOICE OF OPERATIONS FOR THE REMOVAL OF URINARY CALCULI.

He stated that there is no *best* operation; every case of calculus has its special indications, and the surgeon will have the best results who has the best knowledge of all methods of operating and can select the operation which is best adapted to the case. The age of the patient; the size and hardness of the stone; the frequency of recurrence; the condition of the urinary organs, and the results following different methods are the chief factors for the selection of a particular plan in any given case. The age of the patient is important. The average rate of mortality in children is generally given as one to sixteen. In his practice, seventy-one cases operated by the bilateral method resulted in recovery. He saw no benefit in the substitution of litholapaxy. In advanced age every method is more fatal owing to enfeebled strength and increased size of stone. He had, however, operated successfully on seven old men.

The character of the stone is an important factor in the choice of operation. If the stone is small crushing should be resorted to; but statistics show that return of the calculus is more frequent after crushing than after lithotomy. It is asserted that litholapaxy is more thorough in clearing the bladder of débris, but this has not been settled and cannot be definitely settled until more thoroughly reliable reports have been collected.

The state of the urethra, bladder, and kidneys must be determined. In considering the urethra, with a view to litholapaxy, it must be determined how far it will admit instruments. Every operator knows the damage that may be done by starting up inflammatory action in the urethra, and the method should be selected which is least likely to roughen or irritate that passage. The condition of the prostate gland must also receive the careful attention of the surgeon. As long as it is normal in condition and there is no enlargement of it to interfere with the introduction of instruments, the crushing operation may be selected; but if it is enlarged or if it is the seat of a tumor, the cutting operation must be resorted to. The bilateral incision in these cases is often followed by diminution of the size of the gland and a re-establishment of the power of micturition.

In diseased conditions of the bladder, the choice of operation must depend upon the extent of the pathological changes which are present in the viscus. If the condition is not excessive, crushing may be resorted to, with good prospect of good result; but if inflammation has been started, with diminution of the calibre of the bladder, cutting should be chosen, no matter how small or how soft the stone. When pathological changes in the kidney have made much progress, all operations are fraught with danger, and the surgeon should be content with making the last days of the patient as comfortable as possible. When all these things are negative, the environments of the patient should decide the choice of operation. The method should be the one which will best remove all distressing symptoms and render the patient most comfortable.

Of the cutting operations he preferred the medio-bilateral, because

1. It opens up the shortest and most direct route to the bladder; passing from a third of an inch anterior to the verge of the anus to the neck of the bladder, it facilitates the introduction of instruments and the extraction of the calculi.

2. It divides parts of the least importance. The incision following the median line does not encounter any structure of importance, nor does the slight bilateral section of the deeper parts do violence to tissues of vital consequence.

In adult life the death-rate alters somewhat in favor of litholapaxy. As the prostate and urethra enlarge and the parts about the neck of the bladder become more vascular, the danger incident to cutting through them increases. On the other hand, the increase of size makes the performance of litholapaxy comparatively easy and safe. In old age the dangers attending all the cutting operations have increased greatly, but the mortality after litholapaxy is very little higher than it is earlier in life.

The rule in childhood seems to be, litholapaxy for small and medium-sized stones; lateral lithotomy for all above this except for very large stones which must be extracted by the suprapubic operation.

The following conclusions were stated:

1. No operation is adapted to all cases.

2. Litholapaxy is incomparably superior to lithotrity and should always be practised in suitable cases.

3. The suprapubic operation should be chosen for the removal of very large and hard stones.

4. The medio-bilateral operation should be chosen in all other cases.

DR. A. T. CABOT, of Boston, then followed with a paper on

THE CHOICE OF OPERATION FOR STONE IN THE BLADDER.

He thought litholapaxy the choice of operation for stone in most cases. It was therefore his object to consider the objections which have been held against it and to enter upon the discussion of its strong points. German writers have objected that a certain amount of skill is requisite to the performance of the operation. It might be urged with equal propriety that any surgical procedure requires a certain amount of skill in operative procedures. In many of his arguments he coincided with the views expressed by Dr. Briggs. In speaking of the relative mortality of the operations he exhibited a table of statistics which he had prepared from the death-rates attending the methods of extraction. From it he concluded that in childhood there is little of choice between lateral lithotomy and litholapaxy. The death-rate in each is a little over three per cent. In adult life litholapaxy has a slightly lower death-rate than lithotomy. Suprapubic lithotomy keeps its place as a little

more dangerous operation. In old age the danger of cutting is greatly increased.

It is exceptional to see loss of function of any kind follow the cutting operations for stone; after litholapaxy no such loss should occur. The possibility of wounding the seminal ducts by incision through the floor should be considered. The lateral incision has the advantage that while giving more room for the extraction, it wounds at least only one duct. Incontinence is an occasional result of perineal sections owing to their interference with both sphincters of the bladder.

In conclusion, he said that in childhood the mortality after crushing is small; that of litholapaxy and lithotomy is about equal. The crushing operation has the advantage in that it does not wound any of the ducts or seminal vesicles, or rectum. The urethra and bladder of a child will tolerate a considerable amount of irritation. For stones too large for the crushing process, however, we must resort to bilateral lithotomy, and for those too large for this method to the suprapubic. Conjoined manipulation will generally enable us to determine the size of the stone. The character of the stone with regard to firmness may usually be determined by the sensation which it imparts to the sound.

Strictures have generally been named as a contra-indication to the operation of litholapaxy, but this is not usually the case, as the stricture will generally yield sufficiently to dilatation. Enlargement of the prostate may, however, render the operation dangerous.

DR. DUDLEY P. ALLEN, of Cleveland, read a paper on

LITHOLAPAXY IN CHILDREN.

The operation has, he said, come to be regarded as justifiable for the removal of calculi in children, and great results have been achieved by it. Lateral and suprapubic lithotomy have their fields of usefulness, and litholapaxy is rapidly becoming recognized as applicable to a certain class of cases. The essayist had received several letters from prominent foreign physicians expressing their views of the operation. G. Buckstone Brown, of London, and Guyon, of Paris, favored its use in children when suitable to the case. Petersen, of Kiel, Germany, and Kerr, of Canton, China, had not made use of the operation. Guyon considers the term litholapaxy a misnomer, since it presupposes the aspiration of the fragments to be the chief rôle.

The chief advantages claimed for the operation were:

1. The absence of a cutting operation, through the dread of which patients frequently delay operative measures until the stone has acquired a large size.

2. The short convalescence, averaging but a few days.

3. The absence of offensive discharge of urine into the bed and over the thighs of the patient, often producing very annoying and even dangerous consequences. The suffering is commonly very slight and confined to a few days. Patients will not hesitate so long before consenting to its being made, and even should recurrence be more frequent than after lithotomy, the secondary operation is much less to be feared, and of much less serious character. A boy's bladder is more likely to be suitable for the operation than is the bladder of an adult. Finally, the operation is especially adapted to the extraction of medium and small-sized stones. It is important that the instrument be as large as will be admitted, and that it be of good manufacture. The fragments should be removed with the fewest possible insertions of the evacuator. In conclusion, he expressed preference for suprapubic lithotomy for great and hard stones, but an operator of skill in litholapaxy would do well to choose it for those of small size.

DR. J. W. S. GOULEY, of New York, read a paper on

THE CHOICE OF TREATMENT OF URINARY CONCRETIONS.

Owing to the lateness of the hour, he omitted all that portion of his paper which referred to lithotomy. He described the various forms and methods of lithotrity. The operation was admissible where the stone was free and friable and of small size. It may sometimes be done in cases of large stone, or in cases of multiple stone. The urethra must be large enough, and the bladder must be tolerant of operative measures. It is not always applicable to cases of tumor at the neck of the bladder. Advanced disease of the bladder, kidneys, or urethra, contraindicates both lithotomy and lithotrity. In some cases a single operation occupying only two minutes was sufficient. Repeated short sittings he considered greatly preferable to a single prolonged sitting, on account of their less harmful effect on the mucous membrane of the bladder, and the less danger from the use of anæsthetics. Lithotrity at one prolonged sitting cannot with prudence be generalized. There are, however, surgeons who still prefer the operation at one sitting, notwithstanding the fact that the dangers are so much greater.

Litholapaxy is no longer a novelty, and may now be estimated at its right value. The great expectations of its advocates have not been realized, for they have discovered that the operation cannot always be terminated at one sitting; that it is not applicable to many cases complicated by urethral obstruction. They have found that in too many cases the injury to the bladder has led to cystitis and prolonged suffering.

Respecting lithotrity in children, he remarked that very little could be said. Several operators have performed the operation, and the conclusion was that it should be reserved for cases of small stone, in which the operation could be completed at one sitting. In cases where the stone is small and friable, weighing only a few grains, lithotrity is justifiable, but lithotomy is surely the safer operation in such cases. He concluded with the statement that the proper treatment of urinary concretions can be drawn only from a proper study of each case and of each method, there being no general rule as to the method that shall be employed in every case.

SIR JAMES GRANT, of Ottawa, said that stone in the vicinity of his residence was not of common occurrence, but he had operated a number of times. He very much preferred the bilateral method of operation to any other procedure. His operations had generally been performed in that way, and it was very seldom that he adopted crushing. He thought that the deductions of Professor Gouley embraced a large amount of good common sense. The difficulties attending lithotrity and its dangers are very great indeed. Unless it can be brought down to an exact measure, and unless it can be completed at one sitting, as in the case of small stones, it ought hardly to be performed at all. Not long ago he had met one of the most interesting cases he had ever encountered. He had a patient who had suffered from stricture, followed by fistulous openings through the perineum. Erysipelas set in, and a considerable portion of the tissue had

sloughed away. Retention and extravasation of urine ensued. He made an extensive incision, permitting the retained urine to escape freely. After a few days the slough separated, leaving an opening three-fourths of an inch in length in the membranous portion of the urethra. After applying large poultices, he observed that the granulations which sprung up were very extensive and pouting. He then thought that he would try the experiment of introducing the catheter into the bladder. In this he was unexpectedly fortunate, the instrument passing readily. Securing the catheter to the edge of the orifice, he retained it there three days, and treated the granulations with nitrate of silver. As a result he secured complete closure of the opening, and the patient was in a few days able to urinate *per vias naturales*. Systematic dilatation of the urethra was practised for a long time. An operation had subsequently to be performed, but the patient is now well.

DR. TREMAINE expressed satisfaction at the great progress which had been made in the last few years by suprapubic lithotomy. Five years ago, he said, this operation would not have been mentioned in the discussion of this question. To-day it had been named as an operation justifiable in certain cases by every speaker. He then reviewed the dangers which accompany the cutting operations for stone which reach the bladder through the perineum. One of the most important, and one which is too often entirely disregarded, he said, was that of impotence. As evidence of this he referred to eighteen cases of stone, all in young boys, which had been operated upon by a surgeon in Pottsville, Pa. The subjects of the operation have all since grown up, have married, and but one of them has become a father. While there were many other ways of explaining sterility, he thought that under the circumstances so large a number of successive cases argued strongly for its being due to the operation.

DR. GOULEY, in reply to an inquiry, stated that he thought the irritation of the bladder by the fragments of stone, which are likely to be left after crushing, is greatly exaggerated; that the fragments of the worst forms of stone, the pure uric acid calculi, the oxalate of lime stones, etc., do less harm than we are asked to believe. After a stone has been properly crushed—one of the worst forms of stone—it is broken into several fragments. The fragments cause some vesical irritation, no hemorrhage, no ulceration, unless they have been considerably disturbed after the operation. The result is a copious discharge of mucus from the mis-called mucous membrane of the bladder. This mucus very soon adheres to the stones and gives them a thick coating by which they are enabled to slip into the urethra and be discharged through it; so that the bugbear of angular fragments after crushing should not be thought of. Uric acid calculi pass very readily, as has been said, after repeated injections of alkaline fluids. They may sometimes be crushed by the finger in the rectum, a very old method of procedure for the extraction of stone.

DR. R. T. MORRIS, of New York, then read a paper entitled

WHAT DRESSING SHALL LIE NEXT TO THE WOUND?

In bringing the subject before the Section he stated that it was his desire to call attention to a point which is not mentioned by authors. What he would have to say applied alike to fresh wounds and to those undergoing repair and on which a bulky dressing could be placed. He did not doubt that his hearers all used the common antiseptic methods of dressing these wounds. The commonly used dressing of vaseline on any textile fabric was the worst form of dressing that could be applied to a granulating surface. The reason for this assertion was the fact that vaseline or any oil coming into contact with lymph prevents its coagulation, keeps the wound moist and favors decomposition and the growth of organisms. Second, when granulation cells are projected into the lymph they come into contact with the textile fabric and are projected into it. Lint and cotton dressings are even worse than textile fabrics. The perfect type of dressing on a fresh wound would be the same as that on a wound undergoing repair. Suppose that we have a wound that is undergoing repair: if we apply to it a dressing composed of any textile fabric, the connective tissue corpuscles and epithelial cells which form over it shoot up into the fibres of the textile fabric; if then for any reason the dressing has to be removed, we remove with it a large part of the new tissue, and thus the repair which has taken place is in a great measure destroyed. We must, therefore, use in these dressings some fabric which is not textile. Gutta-percha tissue will not altogether fulfil the requirements. Further than this, the moisture which collects under gutta-percha tissue has a disintegrating effect on the granulations and prevents their organization.

Lister's protective oiled silk is the only thing which can be applied to a wound without preventing its repair. The speaker went on so far as to affirm that if we have a blood-clot two inches in length by the same width covered by such a dressing, if fermentation does not occur, and if it is not injured in any way, it will become replaced by fibrous tissue. In large granulating surfaces we should first render the surface entirely aseptic by means of a ten to fifteen volume solution of peroxide of hydrogen; then apply immediately the protective oiled silk. Over this we may apply any absorbent dressing we may desire, absorbent cotton, etc.

DR. H. O. MARCY, of Boston, thought that while there was a great deal of value in what the last speaker had said, he did not think that it applied to operative wounds. He had of late applied no dressing at all after operations, simply closing the wound, drying the skin and applying over it a little iodoform with a few fibres of cotton over it to strengthen the dressing. In this way nature is left entirely to herself and agglutination goes on rapidly. He did not now use drainage tubes as he formerly did.

EVENING SESSION.

DR. J. COLLINS WARREN, of Boston, read a paper on

THE MANAGEMENT AND TREATMENT OF LARGE HERNIÆ.

He said that the large herniæ seem to have a *raison d'être*. In other words, the subject of the hernia usually suffers from some form of disability which prevents him from exercising that control over the hernial tumor which an intelligent and able-bodied person would exercise. In a large proportion of cases, particularly in women, obesity is a strongly predisposing cause. In the male, the subject is either a large middle-aged business man, so absorbed in his work, or of so callous a temperament as to

have neglected his disease until compelled to seek treatment through fear of permanent disability; or he is an old and feeble individual, or so obese as to be unable to effect a reduction of the tumor by manipulation, and to retain it in place by the proper application of a truss. We find large herniæ in children whose position in the social scale is so low that they cannot receive proper care. He narrated several cases illustrating each of the forms of cause referred to. In each case he had applied the treatment which the nature of the case seemed to demand. In none of the reported cases had a radical cure been effected, but the comfort of the patients had been secured.

DR. HENRY O. MARCY, of Boston, then read a paper on

THE RADICAL CURE OF HERNIA BY THE USE OF THE BURIED ANIMAL SUTURE.

Fourteen cases operated upon within the last eight months and illustrating every variety of hernia, and the essayist's methods of operating, furnished the text for this paper. Specimens of hernial sac were exhibited to demonstrate the changes which take place in the peritoneal layer. In old large herniæ the peritoneum was found so thickened and so blended with the surrounding cellular tissue as to be distinctly pathological and utterly devoid of value as an aid in the restoration of the protruded parts. He thought it clearly the duty of the surgeon to remove tissue thus changed. The operation performed by the speaker consisted in dissecting up the sac quite within the ring; then making the neck tense by traction, passing through it a double continuous suture, in the line of the oblique opening across the ring, and resecting the portion of the sac thus separated. The stump is then carried up within the internal ring which, in large and old herniæ, is almost completely closed from below upward by a double suture. In this manner the obliquity of the canal is restored, a point which the speaker considered of the utmost importance. The pillars of the ring are then brought together by a continuous suture extending to the outer margin of the external ring and encroaching closely upon the cord. The overlying tissues, and, finally, the skin, are approximated in the same manner, with a buried animal suture. This is accomplished by means of a running blind stitch connecting the deeper layers of the skin. By this means the essayist claimed the ring is restored, the tissues are held in proper relation, bleeding prevented, and no pockets allowed to remain for the accumulation of secreted fluids. Drainage is, therefore, unnecessary, and the wound after thorough irrigation with bichloride solution is dried and at once closed with iodoform-collodion. Repair goes on without pain, swelling, or even tenderness; opiates are rarely required. The speaker had operated about one hundred times for the relief of hernia, with, so far as he could determine by a recent examination of the traceable cases, about ninety per cent. of cures. The operation he considered without danger except in cases complicated by strangulation, where the integrity of the intestine has been impaired.

He expressed the belief that he had been the first American pupil of Mr. Lister. Soon after his return from Edinburgh he operated on a case, closing the ring in the manner described, because the patient was afflicted with a cough. The result was permanent cure of the hernia. The operation was soon repeated upon others. Being successful he began a careful comparative study of the behavior of animal ligatures incorporated in the living tissues, and found that they were replaced by vitalized connective-tissue cells. His discovery, the priority of which has never been questioned, he considered of paramount importance in all operative procedures, but particularly so in those for the relief of hernia. The essayist expressed his preference for sutures made from the tendon of the kangaroo's tail.

DR. JOHN B. DEAVER, of Philadelphia, under the title of

THE RADICAL CURE OF HERNIA,

described the various operations which have been proposed, including those of Macewen, McBurney, Baker, and Banks. From these he had devised an operation based chiefly upon that of McBurney, and differing from it chiefly in the fact that he permits the fundus of the sac to remain *in situ*. He preferred antiseptic silk sutures.

DR. CHARLES W. DULLES read a paper on

PROPERITONEAL HERNIA.

This, he said, is a subject but little understood in America, but three cases having been reported. One of these was his own, published in 1886, the second by Dr. Hartley, of New York, and the third by Dr. Torrey, of Brooklyn. A properitoneal hernia he described as one occupying an abnormal position within the abdominal or pelvic wall and in front of the peritoneum. In a true properitoneal hernia the tumor lies between the peritoneum and the overlying muscles, if abdominal, or between the peritoneum and the bones, if pelvic. There is also a form of hernia in which the protrusion occurs between the planes of the abdominal muscles, and another in which it lies outside of the muscles and just beneath the skin and superficial fascia. These cases are, for the most part, inguinal hernias in their inception, and are often accompanied by a testicle which had not descended. The obstruction offered by a truss, or the incarcerated testicle at some later period, causes the protrusion to be forced, under a strain, into one of the unusual directions described. Their position is usually above and parallel to Poupart's ligament, and they frequently lead to the production of a hydrocele of the cord. They sometimes become so large as to protrude beyond the ligament and to become pendulous, or extend upward and outward as far as the anterior superior spine of the ilium. Although the essayist had found the record of a case successfully treated by taxis, he considered this the most dangerous method of treatment, and preferred the cutting operation.

THURSDAY, JUNE 27TH.

DR. THOMAS K. MORTON, of Philadelphia, presented

SOME FURTHER CONSIDERATIONS AND STATISTICS OF ABDOMINAL SECTION FOR TRAUMATISM.

He considered of paramount importance the irrigation of the peritoneal cavity. Where there has been extravasation of the contents of the intestine into the peritoneum, irrigation and drainage are the two life-saving factors in closing this operation. The irrigation cannot be too copious; the water should be hot and plenty. If there are perforating wounds of the liver, spleen, kidneys, they should also be irrigated. A glass tube carried down into the wound in the organ would be an advantage. Washing out the stomach is often advisable, especially if the

wound has been received after copious eating and drinking, as is often the case. Rectal alimentation is important in cases where extensive repair of the intestine has been made. He then reported 110 cases which he had collected, with a mortality of 62, all but 16 of them being American. Four times the abdomen had been opened for gunshot wound, where no wound of consequence was found. All recovered. The statistics showed slightly better results for American operations than for foreign, because, as he thought, the operation is performed earlier in America than abroad. The essayist also recommended the use of hydrogen gas for the detection of wounds of the bladder in much the same manner as it is used by Senn for the discovery of perforations of the intestine.

DR. JOSEPH T. PRICE, of Philadelphia, then read a paper on

PELVIC SURGERY BY ABDOMINAL SECTION—ITS PAST, PRESENT, AND FUTURE.

Reference was first made to the early history of abdominal and pelvic surgery and the opposition which they encountered. He strongly favored thorough cleanliness in operations without the aid of any chemicals. Listerism has wrought death by means of chemicals instead of dirt. Delay is not conservatism. He referred also to the former custom of preparing a large collection of instruments for the operation of laparotomy, and the present small number that is considered necessary. Everything is now done to gain cleanliness and speed. The drainage tube, in itself an advance, has now given place to flushing by means of the gravity tube, and the speaker could not too strongly recommend its use. Hemorrhage from faulty tying of the pedicle is a great cause of death after the operation of ovariotomy. Investigation has led to the adoption of animal ligatures.

The treatment of incipient peritonitis is now the use of saline purgatives, or, if they are not well borne, small doses of calomel. Experience has shown that a violent peritonitis, almost or quite general, will yield to this treatment, even though the disease be due to septic cause. The opium treatment can give no such showing as this. The discovery of the dependence of pyosalpinx upon gonorrhœa has given to the latter disease in the female an importance which it never before had. From being looked upon as a trifling malady, it is known to be the cause of the worst form of disease to which the female is liable.

If there is any better treatment of pelvic troubles than the knife, we should look to it with pleasure. The essayist had not, however, much faith in electricity. It has been applied and lauded as a specific for almost every disease in nosology, but the results obtained from it are by no means so gratifying as promised. The essayist did not believe that one-fourth of the reported cases of its successful use as a fœticide had been cases of extra-uterine pregnancy, and many of them, he thought, were not even pregnancy of any form.

DR. J. M. BALDY, of Philadelphia, read a paper on

PERITONITIS.

He first referred to the inaccuracy of early statistics in reference to peritonitis. No safe deductions, he said, can be drawn from the records of post-mortem examinations in this disease more than a quarter of a century ago. With reference to the origin of the disease there was not a unanimity of opinion. That it was never of idiopathic development he was not ready to assert, but he could safely declare that every case that had come under his own observation had been of traumatic origin. The only way in which opium could hold its place in the reputation it had gained in the treatment of peritonitis was on the supposition that it was of idiopathic origin. In the treatment of the disease he recommended drainage and depletion. Our best channel for depletion is through the alimentary canal, and the best method of securing it is by means of large doses of saline cathartics. Reference was also made to the case of Dr. Wiltshire, who, in 1878, deliberately opened the peritoneal cavity in an acute peritonitis, found a strangulated bowel, relieved it, and saved his patient. Such should be the course of treatment whenever possible. If it is a diseased appendix, cut down and remove it as quickly as you would if it were a diseased Fallopian tube. If this method is not followed the patient is sure to die from the peritonitis. The operation should be made whether pus exists or not. Laparotomy is the only hope in such cases. The tubercular form of peritonitis is no exception to the rule, and it is being demonstrated daily that many patients live on for years after the operation. The time may come, as was surmised by Flint, when laparotomy will be as applicable to the treatment of purulent disease of the abdominal cavity as is thoracentesis, the injection of fluid, and thorough irrigation for pyothorax. The time has come!

DR. N. B. CARSON, of St. Louis, then read a paper on

CHYLOUS CYST OF THE MESENTERY, WITH REPORT OF A CASE.

The case to be reported was the only one found in American literature, and up to the present time the largest cyst of the character on record. He first saw the patient about three years ago, had him under observation for three months, then lost sight of him, and did not again see him until five months ago. The history given was about as follows:

Male, aged thirty-nine, phlegmatic temperament, medium height, slight build, well-nourished, weight about one hundred and fifty pounds. Father and mother living; family history good. At twenty-four years of age he had chills; at thirty-four, typhoid fever; and more recently a malarial attack, when his weight was reduced from his former standard—one hundred and sixty-five—to one hundred and fifty. On examination he found a tumor, the size of a fœtal head, midway between the umbilicus and pubes and in the median line. He diagnosticated it a mesenteric cyst. He made an exploratory puncture, and withdrew several ounces of a milky-white fluid. Upon this discovery he altered the diagnosis to "cyst of the receptaculum chyli." During the three months which succeeded upon the aspiration of the tumor the cyst did not fill up. Five months ago, however, he was sent for, and found that the cyst had rapidly filled, and had of late given him much annoyance. The patient's general health had been good, his weight one hundred and fifty pounds, and the only alteration perceptible in the tumor had been in its size.

On March 3d, the tumor was removed by laparotomy. Five pounds of fluid were first withdrawn; the peritoneal surfaces were then stitched together, the cavity filled

with iodoform gauze, the edges brought together, and the abdominal cavity closed.

Examination of the fluid showed its specific gravity 1014; reaction alkaline. There was present albumin but no fibrin, large granular cells with fatty protoplasm. The chief anatomical elements consisted in minute fat granules resembling those of milk and crystals of chloride of sodium in great numbers. The fluid two months after the operation showed no signs of putrefaction. The walls of the cyst were hard, rough, and free from inflammation.

In conclusion, the author reviewed what is known of the pathology of the disease. He advised the removal of the cyst as soon as it begins to interfere with the movements of the patient or to injure his health. In most cases cure can be effected by incision and removal of the cyst.

DR. MORRIS hoped that he was incorrect in understanding Dr. Price to say that he did not use antiseptics. He was aware that Wegner has shown that disinfectants are not ordinarily necessary within the peritoneal cavity. The lymphatics are ordinarily capable of picking up and carrying away all septic matter. Tait says that he accomplishes by hydragogue catharsis what Heath and others accomplish by drainage.

He thought the only occasion for using drainage in the abdominal cavity is where pus is present.

DR. MANLEY, of New York, took a less extreme view of the treatment by purgation. He thought that the bowels should not be permitted to become locked up, but he preferred action upon them by means of enemata to that by purgation from above. Opium must not, however, be too quickly laid aside, for there is no pain which kills more quickly than pain in the abdomen, neither must we too indiscriminately open the abdominal cavity. Opening the abdomen of a man, whose respiratory action is abdominal, is altogether different from opening the abdomen of a woman, and the result is very apt to be different. In a woman everything favors repair, but in a man it is almost impossible to hold the respiratory muscles quiet.

DR. I. N. QUIMBY, of Jersey City, thought free purgation dangerous and asserted that the best results he had been able to obtain were from the free use of opium, preceded by leeches and poultices to subdue the inflammatory action. After this it is proper to get up free purgation. We must resort to the use of the knife cautiously.

DR. JOHN B. DEAVER, of Philadelphia, stated that he had seen several cases in which operation had been performed with the recovery of the patient. He had also read of a great many cases of peritonitis which had recovered without operation, but he did not believe that half of such cases were peritonitis at all.

DR. PRICE, in closing the discussion, said that many cases which are operated upon died, for the simple reason that the operation is resorted to for the purpose of doing an ideal operation, and upon a patient when in a dying condition. The value of purgation in abdominal surgery is vastly more before the operation than after it. It is difficult to use purgatives after the prolonged use of anæsthetics. We have also in just that class of cases an ether mortality, due to the prolonged anæsthesia. There is another class of cases that die from ether which would die without it. The peritoneum will not tolerate dirt or filth of any kind. Mr. Tait minimizes everything about abdominal surgery; he makes the shortest incision through the shortest course as quickly as possible.

DR. ADDINELL HEWSON, of Philadelphia, in a paper entitled

THE USE TWENTY-FIVE YEARS AGO OF POLARITY FOR LOCATING THE WHEREABOUTS OF A LEADEN BULLET DEEPLY EMBEDDED IN THE BODY,

narrated the case of an army officer treated by him in 1863, in which he had located by means of a small compass worn as a watch charm, the bullet embedded in the tissues at a depth of two inches.

DR. THOMAS H. MANLEY, of New York, reported

A UNIQUE CASE OF FRACTURED EXOSTOSIS OF PUBIS.

The case was that of an Italian, nineteen years of age and a resident of the United States for two years. He complained of occasional severe pain in one leg, and was for some time treated for rheumatism, without benefit. Finally he became so accustomed to the pain that he gave it little thought and continued to work regardless of it. One day while employed, he suddenly became weak; the weakness was followed by a chill, and he was taken home. When admitted, two weeks after, he was very weak, had a temperature of 101° F. and a pulse rate of 120 per minute. No organic disease was discovered. The left leg was very much swollen from Poupart's ligament to the knee. An accumulation of pus was diagnosticated in the region of the pubis, and an incision was made for the purpose of evacuating it. A large exostosis was discovered. An operation was then performed for its removal but although the operation was successful, the patient died a short time afterward. Examination of the exostosis removed showed that it was a reduplication of the pubic bone, and that it had been attached to the latter at one extremity. It was in size about four inches long by half as wide.

DR. ROBERT NEWMAN, of New York, next read a paper on

ELECTROLYSIS IN THE TREATMENT OF STRICTURE OF THE RECTUM.

In introduction he stated that he had prepared with great care a paper on this subject which was entirely too long to read *in toto*. He had fourteen cases to report. In 1871 he had made his first operation for stricture of the rectum by electrolysis on a case complicated by five fistulæ. The operation was a complete success. Several years after, the patient dying of another disease, he secured a post-mortem and found that the stricture had not returned. One important feature of this operation was the use in the rectum of a bullet-pointed electrode. In speaking of the disease under consideration, he stated that females are more liable to have stricture of the rectum than are males. The stricture age is between thirty and forty; the youngest of his cases was twenty-four, the oldest sixty-two. Eight cases were single strictures, four multiple, one had three and one had four strictures. The duration of the disease was from six months to twenty years. The causes were various. Constipation was a great cause; other causes were tuberculosis and syphilis. One case was complicated by five fistulæ; only a few cases had had any previous

treatment; only two had had medical treatment, the others surgical. Six had been operated upon with the knife. In none of the cases had the previous treatment been beneficial; some proved to have been entire failures. It must be admitted by the most sanguine operator that proctatotomy must be followed by the use of the bougie at regular intervals. The best results in the treatment of rectal strictures were obtained from the use of the same method as would be employed in the treatment of urethral strictures, except that a stronger current may be used and the sittings may be more frequent. While in the urethra five milliampères would be sufficient, fifteen milliampères may be used in the rectum. The treatment may last fifteen or twenty minutes, and the sitting should be once in every four days.

Among the conclusions arrived at by the author, the following were stated:

Electrolysis in the treatment of strictures of the rectum is not a panacea; on the contrary, failures may happen, and probably ultimately will happen in the strictures due to carcinoma.

Electrolysis will commonly cure rectal stricture when all other methods have failed.

Electrolysis will cure a certain percentage of cases without relapse better than other modes of treatment, and without the necessity of after-treatment or the use of bougies.

The best chances of cure are in cases of fibrous inflammatory stricture.

The best method of treatment is with the metallic bullet electrode as negative pole, a weak current, and treatment every four days.

DR. MEYER, of New York, spoke of the objections that have been urged against electrolysis by some eminent men. He had, however, seen several cases successfully treated by Dr. Newman. One case in particular he recollected; a case of carcinoma that was kept in a condition of comfort for several months by means of his treatment.

FRIDAY, JUNE 28TH.

DR. CHARLES DENISON, of Denver, Col., described

A NEW RIB CUTTER, AND A CASE OF RESECTION OF RIBS FOR DRAINAGE OF A PULMONARY CAVITY.

He reported a case of croupous pneumouia with all the typical symptoms, crisis occurring on the sixth day, but normal resolution not taking place. During the following summer the patient had chills, fever, and night-sweats. The evidences of a cavity in the lung were soon developed, a cracked-pot sound on percussion, cavernous and broncho-vesicular respiration. The sixth and seventh ribs were resected, four ounces of pus evacuated, a rubber drainage tube inserted, and injections of a ten per cent. mixture of salol in liquid vaseline made twice daily. The improvement was rapid and pronounced, the chest expanding, the fever subsiding, and, finally, the expectoration subsiding. In the operation he used a peculiar pattern of rib-cutter devised by himself. Owing to the collapse of the chest-wall which had occurred, he found the ribs so close together that it was almost impossible to insert any of the known bone-cutters. He, therefore, had the instrument made which he exhibited. It combined a periosteum separator and a rib-cutter in such a manner that the point could with ease be forced between ribs lying in contact or overlapping each other and be made to separate the periosteum from the bone for any desired distance, although the opening through the skin had been but a small one. A mechanical joint was so fitted to the jaws of the instrument that the cutting blade could be closed with such force as easily to sever a rib of beef and sticks of wood of considerable thickness, as demonstrated by the author.

DR. J. O. WHITNEY, of Pawtucket, R. I., asked, Is every case of empyema to be treated by exsection of ribs, or by incision between the ribs? Is it necessary in every case to make so radical an operation? He had operated by simple incision, putting in a silver tube, but he found that owing to collapse of the ribs there was soon considerable pain. He suggested the possibility that an instrument which would saw the rib instead of cutting it, if it could be devised would be preferable to the one presented by the essayist.

DR. MCCOMAS, of Deer Park, reported a case in which he had resorted to repeated aspirations of the chest without benefit. An incision was subsequently made, the chest cavity washed out with a solution of chlorate of potash and boric acid, a drainage tube inserted, compound tincture of iodine injected and retained until severe dyspnœa was produced, then let out and the patient made a good recovery.

DR. J. B. HOPKINS, of Philadelphia, then read a paper on the

ABSORPTION OF A STERILIZED DEAD-BONE DOWEL.

The paper consisted of a microscopic study of the phenomena witnessed during the process of absorption of a dead-bone dowel-pin firmly driven into the femur of a dog. As a result of the study, he arrived at the following conclusions: Where sterilized dead bone is placed in contact with living bone, under favorable circumstances, it undergoes absorption; when placed in contact with periosteum, it undergoes organization. These processess go on most actively between the fifth and eighth weeks, and are not associated with inflammatory action. Where these bone dowel-pins are used for any mechanical purpose in surgery, they may be relied upon for a period of a month or six weeks. After this, their services being no longer necessary, they gradually disappear.

DR. MCCOMAS reported the case of a young lady whose arm had been amputated when she was a child of about four years. He stated that four inches of new bone had grown from the stump, and that the new growth is covered by only a thin layer of skin of a bluish cicatricial character, very sensitive. He expected soon to amputate it.

DR. HOPKINS then closed the discussion by reporting a case in which a small portion of the head of the humerus had been retained in an ampuation and had proved of great advantage, chiefly in preventing the deformity which is usually so marked after shoulder-joint amputations.

DR. J. G. CARPENTER, of Stanford, Ky., read a paper on

THE PATHOLOGY AND TREATMENT OF CHRONIC SCIATICA.

In it the author discussed in a very complete manner the various theories as to the production of neuralgia of this nerve, and the *rationale* of the several methods of

treatment, especially of that by nerve-stretching. The various steps of the latter operation were also described in detail. He considered systematic massage as of the greatest importance in the treatment of most cases of sciatica.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, June 4, 1889.

THE PRESIDENT, GEORGE W. JACOBY, M.D., IN THE CHAIR.

DR. W. P. WILKIN reported a case of

ALCOHOLIC PARALYSIS WITH CENTRAL LESIONS,

and exhibited microscopic sections of the cord. The patient was a female, aged thirty-one, and died after four days' stay in Bellevue Hospital with acute alcoholism and alcoholic paraplegia. At the autopsy the liver was found to be fatty and much enlarged, weighing eight to ten pounds; kidneys large, cortex thickened and markings indistinct; brain showed much extravasation around the bloodvessels. There was a leptomeningitis about the spinal cord, especially marked over the posterior part, and involving the posterior nerve-roots. Degenerative changes found in the posterior columns, most marked near the periphery. The interstitial increase was not confined to one system of fibres; it extended to a less degree through the lateral columns of the cord. In the sciatic and tibial nerves considerable increase of interstitial tissue, and in some places a disappearance of axis-cylinders. This case was presented as one of ascending degenerative changes, and as showing that alcoholic paralysis may involve lesions not of the periphery only, but also of the central nervous system. He referred to other cases corroborative of this statement.

DR. DANA then exhibited a case of

SEPTIC PERIPHERAL NEURITIS DUE TO PYELO-NEPHRITIS,

with the following history: John L., aged twenty-one, was admitted to hospital Dec. 13, 1888, with symptoms of acute articular rheumatism affecting all extremities. There was no history of alcoholism or venereal disease. There were pus and albumin in the urine, continuing five weeks. In the middle of January paralysis came on, the rheumatism abating. There were anæsthesia and burning pains. The nerves affected were the ulnar and median of both arms, and the anterior tibial of both legs. Atrophy and degenerative reaction appeared. Improvement began about March 16. Electrical reactions taken in April, 1889, showed complete degenerative reaction in flexors of the right arm and partial in those of the left. Patient is now improving very slowly, but there is still sensory and motor paralysis of arms. He regarded the articular affection as a pseudo-rheumatic disorder due to septicæmia. It had not responded to the usual rheumatic remedies.

DR. SACHS said that if there were any question as to the diagnosis of the nervous affection it would lie between peripheral neuritis and atrophy following joint lesions. But the anæsthesia in this case was conclusive in corroborating Dr. Dana's diagnosis.

DR. JACOBY then read a paper entitled

PERIPHERAL PARALYSIS DUE TO CARBONIC OXIDE POISONING,

in which he reported two cases—one of poisoning by coal gas, the other by illuminating gas. The former contains about six per cent., and the latter eight to ten per cent., of carbonic oxide. The action of this agent on the body is twofold—upon the blood and upon the nervous system. The symptoms of its effect upon the nervous system, as variously reported, had been a burning sensation and reddening of the face, dizziness, tinnitus, headache, nausea, vomiting, unconsciousness, tonic and clonic spasms, involuntary passage of urine, feces, and semen, complete paralysis, coma, and death. In some cases excentric pains in the extremities, as well as sensory disorders of the skin, have been noted. Local or general anæsthesia of the skin has been observed in some cases that have recovered, as well as paralysis of voluntary muscles, most of which latter were of central origin. He had found two cases of peripheral origin in literature. His own cases were briefly as follows:

CASE I.—Male, aged thirty-eight, spent an evening conversing with a friend in a tightly closed room, which was heated by a furnace from below. After a time his face became flushed and hot, he felt dizzy, and his head ached; there was nausea, blackness before the eyes, and six hours' unconsciousness supervened. On attempting to walk, then, he noticed that his right leg was weak and his foot turned in, and the right foot was anæsthetic. The author saw him a week later, and found paralysis of the muscles supplied by the peroneal nerve, and anæsthesia. Electrical reactions normal at first, but degenerative later, with concurrent atrophy.

CASE II.—Female, aged eighteen, attempted suicide with illuminating gas. Her room was broken open and she was found dazed but not unconscious. Recovered senses rapidly, but extensors of the right hand were paralyzed. She gradually atrophied, exhibited degenerative reaction, and in time recovered. Slight anæsthesia.

The author was under the impression that both radial and peroneal paralyses occur most frequently in winter, among the poor occupying illy ventilated rooms heated by stoves, and that mild carbonic oxide poisoning may be a more common cause than we imagine.

DR. SACHS thought that an excellent case had been made out for the author's carbonic oxide theory. Numerous cases of musculo-spiral paralysis generally credited to pressure, might possibly have such origin. It is a suggestion that ought to be entertained.

DR. STARR said the cases reported were interesting and no doubt peripheral in their nature. But we should be cautious in ascribing unilateral paralysis to a general intoxicant in the system. Other poisons occasioning paralysis caused symmetrical lesions, as exampled in alcohol, lead, arsenic, diphtheria, where the injuries are always bilateral. He was aware that, of course, as in lead poisoning, the paralysis was sometimes more marked upon one side than another. This was, therefore, a presumption against the cause ascribed by Dr. Jacoby. What was the cause, then? He described cases of his own of coma, where patients lying for many hours would have pressure paralysis of the ulnar or other nerves. In another case a patient had paralysis of the adductors of the arm after a uræmic convulsion, which was ascribed to the grasp of the attendant. He thought pressure of some sort more

probable as a cause in the cases just portrayed than carbonic oxide.

DR. SACHS stated that carbonic oxide differed from other poisons in the rapidity of its effects. Those mentioned by Dr. Starr were very slow. In such rapid cases it might not be safe to apply the symmetrical rule.

DR. DANA regarded the cases as due to the action of both elements. In comas, for instance, very slight pressure may produce paralysis where ordinarily it does not. The paralyses so frequent in alcoholic intoxication are explicable in this way. Carbonic oxide may affect the system in a similar manner.

DR. JACOBY said that the same objections had been made in cases of ether and osmic acid injections. He did not consider his position beyond question, but with the two other cases in literature added to his own, the theory advanced was tenable.

NEWS ITEMS.

The Prevention of the Spread of Consumption.—The following rules to be observed for the prevention of the spread of consumption were approved last Tuesday by the Health Department of New York City, and ten thousand copies were ordered to be printed for public distribution.

Pulmonary tuberculosis (consumption) is directly communicated from one person to another. The germ of the disease exists in the expectoration of persons afflicted with it. The following extract from the report of the pathologists of the Health Department explains the means by which the disease may be transmitted:

"Tuberculosis is commonly produced in the lungs (which are the organs most frequently affected) by breathing air in which living germs are suspended as dust. The material which is coughed up, sometimes in large quantities, by persons suffering from consumption contains these germs often in enormous numbers. . . . This material when expectorated frequently lodges in places where it dries, as on the street, floors, carpets, handkerchiefs, etc. After drying in one way or another it is very apt to become pulverized and float in the air as dust."

By observing the following rules the danger of catching the disease will be reduced to a minimum:

1. Do not permit persons suspected to have consumption to spit on the floor or on cloths unless the latter be immediately burned. The spittle of persons suspected to have consumption should be caught in earthen or glass dishes containing the following solution: Corrosive sublimate, 1 part; water, 1000 parts.

2. Do not sleep in a room occupied by a person suspected of having consumption. The living rooms of a consumptive patient should have as little furniture as practicable. Hangings should be especially avoided. The use of carpets, rugs, etc., ought always to be avoided.

3. Do not fail to wash thoroughly the eating utensils of a person suspected of having consumption, as soon after eating as possible, using boiling water for the purpose.

4. Do not mingle the unwashed clothing of consumptive patients with similar clothing of other persons.

5. Do not fail to catch the bowel discharges of consumptive patients with diarrhœa in a vessel containing corrosive sublimate 1 part, water 1000 parts.

6. Do not fail to consult the family physician regarding the social relations of persons suffering from suspected consumption.

7. Do not permit mothers suspected of having consumption to nurse their offspring.

8. Household pets (animals or birds) are quite susceptible to tuberculosis; therefore do not expose them to persons afflicted with consumption; also, do not keep, but destroy at once, all household pets suspected of having consumption, otherwise they may give it to human beings.

9. Do not fail to cleanse thoroughly the floors, walls, and ceilings of the living and sleeping-rooms of persons suffering from consumption at least once in two weeks.

Death of Dr. Charles Bland Radcliffe.—We regret to learn of the death, on June 18th, of Dr. C. B. Radcliffe, from the rupture of a varicose vein. Dr. Radcliffe had long held an eminent position as an authority on nervous disease and as a highly esteemed writer on questions of nerve force, especially in its electrical relations.

The Pentacle of Rejuvenescence.—On two occasions this month Dr. Brown-Séquard has made communications of a most extraordinary nature to the Société de Biologie of Paris. The statements he made—which have, unfortunately, attracted a good deal of attention in the public press—recall the wild imaginings of mediæval philosophers in search of an *elixir vitæ*. He obtained by compression and washing from the testicles of young animals a fluid, which he injected into the subcutaneous cellular tissue with a hypodermic syringe. He performed the experiment on himself, repeating the injection almost every day for a fortnight, with results which appeared to him to warrant an immediate communication to the Society. He stated that he had experienced a rejuvenescence of all his forces, physical and psychic; all that had become difficult or impossible for him owing to advancing age became once more easy, and he found himself possessed of the same vigor as he had had thirty years before. He could undergo fatigue in standing, travelling, and in intellectual labor previously impossible; the functions of defecation and micturition also were discharged with greater ease. MM. Féré and Dumontpallier, in commenting on M. Brown-Séquard's statements, observed that they would require to be rigidly tested and fully confirmed by other self-experimenters before they were likely to meet with general acceptance; and in this opinion we fully concur.—*British Med. Journal*, June 22, 1889.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LV. SATURDAY, JUNE 20, 1889. No. 3.

ORIGINAL LECTURES.

THE SURGERY OF THE CENTRAL NERVOUS SYSTEM.

Address before the Medical and Chirurgical Faculty of Maryland, April 24, 1889.

BY RANDOLPH WINSLOW, M.A., M.D.,

PROFESSOR OF SURGERY IN THE WOMAN'S MEDICAL COLLEGE OF BALTIMORE.

MR. PRESIDENT AND GENTLEMEN: It has fallen to the lot of my predecessors to record from time to time the many advances in the surgical art which have taken place during the present decade. Under the beneficent influence of antiseptic principles the various cavities of the body have been boldly invaded by the surgeon, and most of the viscera subjected to the operator's knife. It is but repeating an oft-told tale to mention the surpassingly brilliant achievements of abdominal surgery. The dread peritoneum of a few years ago has become the most tractable of all membranes, so that with proper care intra-abdominal operations are attended with a very small mortality indeed. The wonderful feat of Lawson Tait, who performed over one hundred and thirty consecutive ovariotomies without a death, stands unparalleled in surgical performances. Operations on the liver, kidneys, stomach, and intestines are followed by most gratifying results. The invasion of the thorax for surgical purposes has become a frequent occurrence; the drainage of the pleural cavity is often performed; the removal of large portions of the thoracic walls for the cure of chronic empyema is successfully undertaken; and even the resection of portions of the pulmonary tissue for neoplastic growths has been safely done. An attempt was made a few years ago by Bloch to resect a lobe of the lung for tuberculosis, but the patient died in twenty-four hours, and the surgeon, chagrined and filled with remorse, terminated his life with his own hand.

Only a few years ago, a celebrated surgeon declared that the limit of operative surgery had probably been reached, but in the short time which has elapsed since this statement was made, some of its most momentous advances have occurred. Amongst all the magnificent achievements of modern medicine and surgery, there is none in which diagnostic acumen and operative dexterity are shown to a greater degree than in the new and but partially explored field of cerebral surgery. I therefore desire to direct your attention to the subject of the surgery of the central nervous system.

By brain surgery I do not mean those cranial injuries which are accompanied with external marks, which serve as guides to direct us to the seat of trouble, but the various intra-cranial affections which make their presence known by signs dependent upon the disturbance in the functions of the parts involved.

Before beginning the consideration of individual lesions, let us briefly call to mind something of the anatomy and physiology of the brain and its coverings. Dr. Keen, at the Congress of American Physicians and Surgeons held in Washington in September, 1888, describes the brain as consisting of a number of viscera, rather than as one organ, and this view simplifies our conception of the brain and its functions very much. The functions of the different portions of the brain have only been partially determined, certain areas are known to preside over certain functions, whilst the functions of other areas are not understood. Marvellous results have followed experimentation upon animals and most of our knowledge of the functions of the brain has been obtained in this way; doubtless increased understanding of the mysteries of this most important structure will yet be obtained by experimentation on animals, by clinical and post-mortem observations, and by the electrical stimulation of the exposed human brain during the performance of surgical operations.

The portions of the brain which are amenable to surgical procedures are chiefly found in the cortex, the base of the brain and its internal ganglia being for the most part inaccessible to operative measures. The frontal lobes, whilst sufficiently accessible, do not always present enough clinical evidence of the pathological condition to justify an operation. As we go backward we come to the motor region which is mostly grouped around the fissure of Rolando, but it involves also the hinder parts of the first and second frontal convolutions, whilst the centre for articulate speech is found in the third frontal convolution on the left side in right-handed persons, in the same convolution on the right side in those who are left-handed. In the pre- and post-Rolandic convolutions and the paracentral lobule we have the centres for voluntary motion; those portions which preside over the motions of the lower extremity occupying the upper, those for the upper extremity, the middle, and those for the head and neck, the lower part of the motor area. The occipital lobes probably preside over vision, and the temporo-sphenoidal lobes are largely concerned in hearing.

Lesions of the cortex of the brain are made manifest by disturbances in the functions of the affected parts, especially in the motor region, where irritative lesions give rise to spasms of the special group of muscles which has its centre at the point of irritation, and destructive lesions produce paralysis of the same set of muscles.

TUMORS OF THE BRAIN.

Tumors of the brain occur more frequently than is suspected by most practitioners, and have been regarded as almost hopeless, until within the last five years. Now the brain has been subjected to surgical treatment, and cerebral tumors are removed with wonderful success. Let us inquire into the nature of brain tumors before

proceeding to consider the propriety of attempting their removal.

The most important investigations into the nature of tumors of the brain have been made by Dr. W. Hale White, of London (*Guy's Hospital Reports*, 1886), who carefully studied the records of 100 brain tumors found in the dead-house of Guy's Hospital from 1872 to 1884. Of these 100 cases of tumor of the brain 45 were tuberculous, 24 gliomata, 2 glio-sarcomata, 5 carcinomata, 4 cysts, 1 lymphoma, 1 myxoma, 5 gummata, and 3 undetermined. Of these 100 tumors only 9 could have been removed, provided the diagnosis could have been made, but it is not probable that more than one could have been accurately diagnosticated and successfully extirpated. Tuberculous tumors are especially unfavorable for operation, as the disease is usually found to involve other organs as well. Of the forty-five cases in White's list there was not one in which other organs were not involved. Bergmann is opposed to all operations for the removal of tuberculous and gummatous tumors, as the former are almost incapable of being diagnosticated, or of being thoroughly removed, whilst the latter require medical rather than surgical treatment. In one case, at least, has Horsley removed a tuberculous tumor of the brain, and Macewen claims to have done the same thing.

The diagnosis of cerebral tumors is frequently very difficult, as in some regions they give rise to no symptoms, whilst in others it is impossible accurately to locate the tumor, though it may be known that a tumor is present. Dr. Seguin says (*American Journal of the Medical Sciences*, Aug. 1888) the diagnosis of a case of supposed cerebral tumor should be worked out in five directions: 1. The diagnosis of a tumor of the brain. 2. The location of the tumor. 3. The depth of the tumor. 4. The solitude or multiplicity of the growth. 5. The nature of the tumor.

First. The diagnosis of a cerebral tumor is usually easily made by an experienced physician, when it gives rise to symptoms, but there may be a tumor without symptoms, especially in the frontal lobes. The most characteristic signs of cerebral tumor are headache, convulsions, local or general paralysis, partial anæsthesia, optic neuritis, hemianopsia, coma, stupor, and slow pulse, which are grouped according to the exact location of the growth. The cranial nerves are liable to be pressed on, and to cause either paralysis or spasms of the muscles which they supply. Aphasia and unsteadiness of the gait are also suggestive of an endo-cranial tumor.

Second. The location of the tumor. As has been said, portions of the cerebrum are very tolerant of pathological lesions, and a tumor affecting these areas may give rise to no localizing symptoms. The frontal lobes, and portions of the temporal, parietal, and occipital lobes, belong to this category. There will be general symptoms of cerebral disease, but no special symptoms. There is left then the central portion of the cerebral cortex, which is known as the "motor area," and which is grouped around the fissure of Rolando. Lesions of this area give rise to symptoms which serve usually to locate accurately the seat of the disease. There are besides certain areas in the occipital lobes, which preside over vision, and a tumor involving this region will cause half vision in both eyes on the side opposite to that in which the tumor is seated. The first temporal gyrus seems to be the organ for the perception of spoken language. Tumors of the motor zone give rise to symptoms which vary with the seat of the growth, which symptoms are spasms or paresis of the muscles to which the fibres from these zones are distributed.

In order to localize the seat of the tumor there are certain first or "signal symptoms" which must be carefully inquired into and studied; later, as the tumor increases in size and invades surrounding areas, these signal symptoms are obscured by other signs. Suppose a tumor originates in the lower half of the middle portion of the motor area, the first sign would probably be a spasm or paresis of the opposite thumb and fingers, gradually extending to the face and tongue, probably producing aphasia if the left side is involved, and finally terminating in permanent paralysis of the hand and forearm. When the first spasm is limited to a small area the patient retains consciousness and watches the convulsive movement with interest or anxiety. When tumors occupy the sensory zone, their presence is made known by hemianopsia or half vision, if they are situated in the occipital lobes, and by ataxia or staggering gait when the growth presses upon the cerebellum. Dr. Seguin says, "a patient who has headache, vomiting, choked disk, dulness tending to stupor, increasing hemianæsthesia, with lateral hemianopsia, without hemispasm or hemiplegia, quite certainly has a tumor in the white substance of the occipital lobe. When with general symptoms of cerebral tumor there is present lateral hemianopsia, as almost the only localizing symptom, there is almost certainly a tumor on the mesial aspect of the occipital lobe, opposite to the dark half fields, compressing and destroying the cuneus." As the tumor grows it may encroach upon the motor area, causing paralysis of the lower extremity, or by downward pressure on the cerebellum may cause ataxia.

Third. The diagnosis of the depth of the tumor. Dr. Seguin stated that the study of lesions of the human cortex and associated fasciculi does not furnish corresponding data for a diagnosis, and that "it is impossible to distinguish a cortical from a subcortical tumor by the character of the convulsions observed." In favor of strictly cortical or epicortical lesions are localized clonic spasms, epileptic attacks beginning as local spasms and followed by paralysis, early appearance of local cranial pain and tenderness, and increased local cranial temperature. In favor of the subcortical location of the tumor are local or hemiparesis, followed by spasms, predominance of tonic spasms, absence, small degree, or late appearance of headache and tenderness to percussion, normal cranial temperature. These symptoms are by no means absolutely diagnostic.

Fourth. The solitude of the tumor. It will usually be possible to diagnosticate the solitude or multiplicity of cerebral growths, by taking into consideration the character of the growth and the complex of symptoms present. Thus a person with tuberculosis presenting at the same time signs of cerebral tumor, is likely to have more than one secondary focus in the brain. Also when there are tumors in different portions of the brain each growth may cause special localizing symptoms. It is not always possible, however, to diagnosticate the solitude of the tumor.

Fifth. The nature of the tumor. We may suspect cerebral tumors to be tuberculous, cancerous, or gum-

matous if they occur in persons who have had like diseases in the external parts or in other organs, and in such cases operation is contra-indicated. In other forms of tumor the diagnosis cannot be made. Tuberculous tumors form 23 per cent.; gliomata, 13 per cent.; sarcomata, 13 per cent.; hydatids, 5 per cent.; cysts, 4.6 per cent.; carcinomata, 4 per cent.; gummata, 3.6 per cent.; with a few of many forms of neoplasm.

CRANIO-CEREBRAL TOPOGRAPHY.

There are various methods of determining the relation of the cranium to the different convolutions and fissures of the brain, but in operating for the removal of tumors a large portion of the skull must be removed, and it is not difficult to expose the growth.

The *fissure of Rolando* is the most important position to locate in operations on the motor area, as from this line we can map out a growth in any part of the motor region of the cortex. This fissure may be found by drawing a line directly backward seven centimetres from the external angular process of the frontal bone, and from the posterior end of this line raising a vertical three centimetres; the upper extremity of this vertical line will correspond to the lower end of the fissure of Rolando. The upper end of the fissure may be found by taking a point five centimetres behind the bregma. The bregma can usually be felt, or can be located by drawing a line through the external auditory meatus at right angles to a horizontal base line drawn from the base of the upper incisor teeth to the base of the occiput.

Reid's method of determining the position of the fissure of Rolando is to erect two verticals, one in front of the ear and the other behind the mastoid process, at right angles to a base line running from the infra-orbital margin through the auditory meatus to the external occipital protuberance. The fissure of Rolando will be represented by an oblique line running from behind forward from the top of the posterior vertical line to about the middle of the anterior line.

Probably the best method of locating the fissure of Rolando is by halving the line from the glabella to the external occipital protuberance; the top of the fissure lies half an inch behind the centre of this line, and in most cases forms an angle of sixty-seven degrees with the sagittal suture. A very useful instrument has been constructed of soft iron, consisting of a long arm one-third of an inch wide and ten inches long, from the middle of which a short arm, six inches in length, branches off at an angle of sixty-seven degrees. When this instrument is properly applied, the short arm lies over the fissure of Rolando.

The *fissure of Sylvius* can be located by a line drawn from a point one and a quarter inches behind the external angular process upward and backward to a point three-quarters of an inch in front of the parietal boss.

Having made the diagnosis of a tumor involving the cerebral cortex, and having determined upon its removal, the growth must be accurately mapped out on the shaven scalp, and the patient prepared for the operation. The day before that of the operation the head is shaved and washed with soft soap and ether, the position of the tumor determined and marked on the scalp, and the head covered with lint soaked in a 1:20 solution of carbolic acid, oiled silk, and cotton-wool, which is allowed to remain on twenty-four hours. The bowels are moved by a purgative the day before, and by enema on the morning of the operation. Chloroform should be administered in preference to ether, owing to the great cerebral congestion which the latter produces, and it is well to give a hypodermatic injection of a quarter grain of morphia previous to the operation, in order to assist in producing contraction of the bloodvessels, and thereby to diminish the hemorrhage. Dr. Keen recommends ergot for the same purpose. Mr. Horsley prefers to follow the full antiseptic details of Listerism in his operations on the brain, but most surgeons are satisfied with the ordinary antiseptic methods.

OPERATIVE TECHNIQUE.—Horsley strongly recommends making a large curved flap instead of the usual crucial incisions, as the soft parts are more easily held out of the way when the flap is curved. The bone should be removed freely with the large trephine and ronguer, and the buttons carefully preserved in hot, carbolized cloths, in order that reimplantation may be done if it seems desirable to do so. The dura mater should be divided an eighth of an inch from the margins of the opening in the bone, and to the extent of four-fifths of the exposed area. The middle meningeal artery should be secured by a ligature passed through the dura mater before it is divided. Hemorrhage from the pia mater will have to be arrested by ligature of the bleeding vessels, which is also the best method of arresting bleeding from the brain itself, though this is difficult, as the cerebral vessels are very friable, and the ligature must be applied very gently. Upon division of the dura the brain may at once bulge into the cranial opening, if the pressure is great, and the tumor be exposed to palpation and sometimes to sight. At times the surface of the brain is discolored at the seat of the tumor; at other times there is no noticeable pathological condition, the brain appears to be normal, and the tumor is situated deeply in the cerebral substance, and usually can be detected as a hard lump, by palpation.

The tumor may be enucleated by tearing through the intervening brain-tissue with the end of the finger or the handle of a spoon. Even where a large tumor has been removed, the cavity in the brain-substance does not remain long, as its base is rapidly raised up almost to the level of the cranial opening.

Drainage should be made as in any other wound, and a perforated rubber tube may be employed for this purpose. Horsley recommends removing the tube in twenty-four hours, but Weir thinks it may safely be allowed to remain for two or three days. After all oozing has been arrested by gentle pressure with a soft sponge, the dural flap is sutured with fine silk or catgut sutures, and the fragments of bone may be reinserted in position. The scalp is now securely sewn in place, and an antiseptic dressing applied, of iodoform, carbolic acid, or sublimate gauze, according to individual preference. The dressing is quite firmly applied in order to diminish the chances of the formation of a hernia cerebri. There are many details in regard to operative technique and after-treatment which, though worthy of discussion, must be omitted from this report.

DANGERS OF THE OPERATION.

First. Sepsis. The operation must be thoroughly aseptic.

Second. Hemorrhage. This is a very fruitful source of danger, and it is a very troublesome complication. The vessels should be seized with clamps and ligatured, or the clamps may be left in the wound for twenty-four hours or more, an effective antiseptic dressing being applied.

Third. Œdema of the brain. This is a complication which frequently follows interference with the brain.

HISTORICAL SKETCH OF THE OPERATION.

In tracing the history of the operation of opening the skull for the removal of a tumor, we see that it is absolutely a production of our own day and generation, since it has only been possible to locate accurately lesions of the brain a very short time. Probably the first operation for the removal of a cerebral tumor was performed by Durante, of Rome, in May, 1884, who removed a tumor as large as an apple, and the patient recovered. The growth was situated in the frontal lobe on the left side, the symptoms being vague: loss of memory and smell, with some displacement of the eyeball, being the most prominent. This operation was reported by Professor Durante at the Ninth International Medical Congress, and had not attracted much notice up to that time.

The first operation which attracted immediate and universal attention was that performed by Mr. Rickman John Godlee, on November 25, 1884, the diagnosis having been made by Dr. J. Hughes Bennett, of a tumor involving the upper third of the fissure of Rolando. The patient died on the twenty-eighth day after the removal of the tumor. This operation is chronologically of the greatest importance, as it demonstrated the feasibility of the operation and supplied valuable information which has since been utilized. Hirschfelder and Morse, of San Francisco, followed with an unsuccessful case.

To Mr. Victor Horsley, of London, is due the marked impetus in regard to the removal of cerebral tumors, his first case having been operated on, on October 9, 1886, with success. Since then operators in England and America have extirpated these tumors, with ever-increasing success. Several cerebellar tumors have also been removed, but as yet no patient has recovered. I do not see, however, why it may not be possible to excise successfully neoplasms of the cerebellum. It is not always easy to tell whether the ataxic symptoms of a case are due to a growth within the cerebellum or to pressure upon the cerebellum by a tumor originating elsewhere. In a case recently under the observation of Prof. Preston and myself, at the Hospital of the Good Samaritan, the cerebellar symptoms were very distinct, but at the autopsy the tumor was found to have its origin in the corpus callosum and to press upon the cerebellum secondarily. This tumor could have been removed without much difficulty if the friends of the patient had not declined an operation.

CYSTS OF THE BRAIN.

Several cases of cystic disease of the brain have been operated upon; some of them with success. The symptoms and operative procedures do not materially differ from those described above in connection with cerebral tumors.

EPILEPSY.

For a long time it has been known that epileptiform seizures are liable to follow injuries to the head, when the cranial lesion presses upon or irritates the cerebral cortex. Many successful operations of trephining for traumatic epilepsy have been performed. My father, Dr. Caleb Winslow, thirty years ago operated on a man for traumatic epilepsy, successfully. When there is a clear history of injury to the head, and pain or epileptic seizures supervene, it is but rational to remove a portion of the calvarium at the seat of injury, and frequently a depressed bit of bone or spicules of bone pressing upon and irritating the meninges and cortex will be found. Sometimes an accumulation of serum or other inflammatory products will be found, and upon its evacuation the epileptic attacks may cease. Of 82 cases of trephining for traumatic epilepsy, collected by Walsham, of London, 48 were permanently cured, 13 improved, 4 not improved, and 17 died; 9 deaths were due to suppurative meningitis.

Spontaneous or idiopathic epilepsy is believed to be due to discharging lesions of the cerebral cortex, as enunciated by J. Hughlings Jackson; and, in inveterate cases after the failure of other therapeutic measures, it is justifiable to expose the brain by trephining and excise the focal centre which appears to be involved. This has been done successfully by Horsley, Keen, Nancrede, Macewen, Bergmann, and others; but we must remember that medical means should be exhausted before resorting to so serious a procedure. In order to determine what portion should be excised, it is essential that the history of the attacks should be accurately learned, and the patient placed under skilled observation, so that the localizing symptoms may be carefully noted. In this manner it is learned what muscles are primarily affected, and, by the excision of the centre presiding over this group of muscles, the spasms are greatly diminished in frequency and intensity or arrested altogether.

Some very remarkable results have been obtained by Horsley; Keen, and others by the excision of discharging centres. As it is impossible to locate such a small portion of the cerebral cortex as the centre for any one set of muscles, as for example that for the thumb, by any rigid rules, it is necessary to find some means of determining the part to be excised, in order that no more of the brain substance may be removed than is required for the purpose; fortunately, we have a means in the electrical stimulation of the exposed area. The application of a weak faradic current to the discharging centre will cause epileptiform spasms in the group of muscles which are presided over by this centre.

The excision of portions of the cortex for epilepsy is a direct sequence of the recent advances in our knowledge of the anatomy and physiology of the nervous system; and, whilst the future of the operation appears brilliant, caution must be exercised lest unnecessary operations should be performed. We have seen the wonderful results of abdominal surgery, but most of us cannot but believe that operative fervor has caused the sacrifice of barrelsful of ovaries and tubes, which ought to have remained where nature put them.

When a portion of the motor area is excised there is at once a complete paralysis of the muscles which are

in connection with this portion, but, in the course of time, a species of collateral functional activity seems to occur, and most of the paretic muscles recover their power, leaving perhaps a very limited group of muscles permanently paralyzed.

ABSCESS OF THE BRAIN.

Intracranial suppuration following fractures and injuries to the skull is a complication which is well known, and the treatment of which by trephining and drainage has, in numerous instances, been attended with success. Beside the collections of pus which are found at the seat of injury between the bone and dura, or subdural, it is not very infrequent for abscesses to occur in the brain substance, hence the surgeon should not be satisfied with simple trephining in cases which present symptoms of intracranial suppuration. When no pus is found when the button of bone is removed, he should go through the dura, and, if pus is not found, an exploration of the brain with a disinfected director or aspirating needle should be made. If pus is found in the brain, it should be evacuated and the cavity drained. There are also brain abscesses which are either idiopathic or, at least, their causes are not discovered, and these may be submitted to surgical treatment if the diagnosis can be made..

A very important variety of cerebral abscess is that which is consecutive to suppurative inflammation of the middle ear or the mastoid cells, of which numerous cases have been observed, and a number of them successfully operated on. The case of the late Roscoe Conklin is still fresh in our memory. The abscess may result from a septic phlebitis extending from the middle ear to the white substance of the brain, or from an extension of the inflammation to the dura mater. The abscess will probably occur at a point one and one-fourth inches above and the same distance behind the centre of the bony meatus of the ear. Mr. Barker calls attention to the subnormal temperature which is found, especially toward night, in cases of cerebral abscess due to ear disease. The patient takes cognizance of inquiries, but answers with deliberation, and this "sluggish but perfect cerebration" is a symptom of cerebral abscess. Usually, when an abscess is present, the dura bulges into the trephine hole, but does not pulsate. Macewen, in addition to the usual method of operating, scrapes out and disinfects the middle ear, and the disinfection of the frontal sinus should also be carefully attended to in any operation upon the brain in which this cavity is opened, as it prevents the access of air through the nasal cavities and helps to diminish the risk of infection.

INTRACRANIAL HEMORRHAGE.

Hemorrhage from the meningeal or cerebral vessels, as the result of trauma, is also recognized as being within the domain of surgical interference. If there has been a fracture of the skull, and symptoms of compression soon supervene, after a period of consciousness, it is almost certain that an intracranial hemorrhage is taking place, and no surgeon ought to hesitate to penetrate the dura mater, evacuate the blood, search for the bleeding vessel and ligate it. Sometimes, after an injury to the head without fracture, symptoms of compression gradually supervene, and in this case the skull should be trephined, depending upon focal symptoms to guide one to the seat of hemorrhage. Krönlein, of Zürich, recommends, in cases presenting symptoms of hemorrhage from the middle meningeal artery, without external lesions, that the trephine be first applied about one inch to one and a half inches from the external angular process of the frontal bone, but, if no hæmatoma is found, to apply the instrument again on the same horizontal line at the point where a vertical line from the posterior border of the mastoid process crosses it. Thiersch, in one case, removed three trephine buttons before the clot was found.

Excellent results have followed trephining closed skulls for hemorrhage, Krönlein saving two out of four cases in what would have been otherwise fatal affections. Several cases have been reported of late trephining for symptoms of compression where the formation of an abscess was suspected, but which proved to be a hæmatoma, the removal of which was followed by recovery. The chief symptoms of hemorrhage are, 1st, an interval of consciousness after injury; 2d, hemiplegia on the opposite side, frequently with convulsions; 3d, slow and hard pulse; 4th, slow, labored, and stertorous respiration.

SURGERY OF THE SPINAL CORD.

Operations upon the spinal cord are of even more recent development than those upon the brain, and as yet only a very few cases have been reported of the removal of tumors within the spinal canal. As far back as 1882, Dr. Carl Maydl, of Vienna, conceived the project of resecting the whole thickness of the cord, and, after some successful experiments on dogs, actually opened the spinal canal of a man for that purpose, but found the conditions too unfavorable to proceed further. The patient recovered from the operation, but was not improved at all. I consider this one of the boldest surgical conceptions on record, and, as such, worthy of remembrance.

Resection of the vertebral laminæ for the purpose of relieving pressure upon the cord resulting from Pott's disease or from traumatism, was first performed by that great surgeon, Dr. William Macewen, of Glasgow, in May, 1883. The first case was one of paraplegia with incontinence of urine and feces, due to a connective-tissue tumor at the seat of angular curvature of the spine. A boy, absolutely paraplegic for eighteen months, was completely cured by resection of the posterior vertebral arch, and removal of the connective-tissue growth at that point. Dr. Macewen has operated on six cases presenting similar symptoms to those of this case, with the result of curing or greatly alleviating four of the cases, with one death, which was possibly hastened by the operation, and one death months after the operation from an extension of the tubercular disease. This is a most interesting field, and one well worthy of careful cultivation.

TUMORS OF THE SPINAL CORD OR MEMBRANES.

Mr. Victor Horsley, a young man, an adept in physiology, pathology, neurology, and surgery, has done more than any other person to create the new department of cerebral surgery, and to him is also due the credit of first successfully removing a tumor from the

spinal dura mater, which, by its pressure on the cord, had produced for four years the most unendurable agony with paralysis. The patient was cured after resection of the third, fourth, fifth, and sixth vertebral arches and incision of the dura mater, when a tumor was found and easily enucleated. Dr. J. B. Deaver, of Philadelphia, is the only American, as far as I am aware, who has operated for the removal of a tumor within the spinal canal. No tumor was found except that due to an osteitis of the vertebræ. The patient died from supposed inhibition of the phrenic nerve, and the case is only mentioned as being of interest in the history of the development of this branch of surgery.

ORIGINAL ARTICLES.

A PRELIMINARY NOTE ON THE USE OF EUCALYPTUS IN HEADACHE.

BY MORRIS J. LEWIS, M.D.,
PHYSICIAN TO THE INFIRMARY FOR NERVOUS DISEASES, AND TO THE CHILDREN'S HOSPITAL,
AND
G. E. DE SCHWEINITZ, M.D.,
OPHTHALMOLOGIST TO THE INFIRMARY FOR NERVOUS DISEASES, AND OPHTHALMIC SURGEON TO THE CHILDREN'S HOSPITAL.

A BRIEF history of the following cases, where the use of oil of eucalyptus was beneficial in relieving headache of various types after other means had failed, is here put on record in order that others may try this remedy as a therapeutic measure in a class of cases in which it has been used with asserted success,[1] but certainly without extended trial. Our own attention was called to this use of the oil of eucalyptus on account of the markedly beneficial effect in Case I., presently to be described, where it was exhibited to control headache believed to be of malarial origin, quinine having failed. The sudden and surprising improvement which followed its use led us to employ it in other forms of functional headache not due to eye-strain or similar removable cause.

CASE I.[2]—Susan B., æt. forty-eight, single. Marked history of malaria and rheumatism. Formerly had severe head-pains once in two months, lately violent occipital headache every other day, with zig-zag lines and hallucinations as prodromes, entirely unrelieved by quinine. With the exhibition of five minims of the oil of eucalyptus six times a day the headache completely disappeared. Examination of the eyes revealed slight refraction error, the correction of which did not alleviate the pain.

CASE II.—Mrs. D., æt. thirty-one. Nervous family history, menstruation irregular and too free, headaches grouped about periods, no apparent eye-strain, indiscretion in diet sometimes appears to precipitate headache which is not a hemicrania, but general and mostly occipital and congestive in type. If headache is not due to dyspeptic attack, eucalyptus will usually abort it, one capsule (five minims) four or five times a day. Her plan is first to take aromatic ammonia and if no relief is afforded then eucalyptus. Antipyrin and cannabis indica gave no relief.

CASE III.—Mrs. T., æt. forty-six. Gouty family history, menopause, headaches for years, mainly in occipital region, congestive in type, any increase of blood in head greatly increases pain, doubtful malarial history, quinine in full doses sometimes lessens attack, salicylate of soda at first gave relief, but caused dyspeptic symptoms, likewise cannabis indica; antipyrin unless given in heroic doses is useless. Patient was placed on rigidly restricted diet, and given five minims of oil of eucalyptus four times a day, with marked benefit. Subsequently the administration of a few doses of the drug sufficed to ward off any severe attack. Eyes were normal, no asthenopia. Patient reports a sister greatly relieved by the same remedy given by another physician at her solicitation.

CASE IV.—Miss L. W., æt. twenty-eight. Right-sided frontal headache. Attacks formerly accompanied by visions, lately has silver rings constantly before eyes. Cannabis indica gave but little relief, eucalyptus gave great relief, headaches much better lately; no malarial history. The eyes revealed results of former granular lids, and the headaches were never in apparent association with eye-strain.

CASE V.—Miss C., æt. twenty-five. Menstrual irregularities. No former severe illness. No history of malaria. Headaches for twenty years, chiefly on left side, bearing no relation to menstruation, congestive and lasting several days. No apparent eye-strain. Iron and arsenic were prescribed for the anæmia and oil of eucalyptus in the event of headache. With the prodromal symptoms of a headache, twenty minims of the drug, served in the belief of the patient to abort the attack.

CASE VI.—Mrs. G., æt. thirty-three. Gouty family history; pelvic peritonitis three years ago; a great sufferer from "hay fever;" frequent attacks of tonsillitis; the patient in girlhood had lived in a malarious district. For years she has been the victim of the most violent occipital headaches of a congestive type, beginning with the feeling of a band in the back of the neck, succeeded by a thumping pain in the occiput which rapidly spreads over the entire cranium and is associated with intense injection of the conjunctiva and swelling of the face. The eyes showed a low grade of hypermetropic astigmatism and 10° of insufficiency of the internal recti. Appropriate glasses were ordered, and prisms for the relief of the muscular defect, with the result of ameliorating the asthenopia, but not materially influencing the headache. A prolonged course of all the usual remedies employed for the relief of headache of a congestive type was ordered, but without any very satisfactory results. Oil of eucalyptus, five minims every four hours, gave great relief even during a paroxysm, but was most efficient when exhibited during a prodromal period, or when taken after such exposure, like cooking, which was always succeeded by a headache. The ability to abort a paroxysm was a marked feature of the medication.

CASE VII.—Miss S., æt.. twenty-one. Nervous and with a nervous family history; anæmic and

[1] United States Dispensatory.
[2] University Medical Magazine, May, 1889.

suffering much from enforced loss of sleep; was subject to violent neuralgic headache uncontrolled by the ordinary remedies and not relieved by treatment of a slight ocular defect. Oil of eucalyptus in five-minim doses produced better results than any other remedy; indeed, while the patient continued its use the headaches were practically absent, although they returned when this was discontinued. There was no history of malaria in this case.

CASE VIII.—Miss L., a plethoric woman, æt. nineteen, the subject of hemorrhoids; slight leucorrhœa and sharp frontal with dull occipital headache brought on by fatigue, by the use of the eyes and often without apparent cause, usually worse in the first few hours of the morning. Both eyes hypermetropic with insufficiency of the external recti of four degrees, the correction of which did not stop the headaches, nor was medication directed to the regulation of the portal circulation followed by relief in this direction. Eucalyptus was the means of producing marked relief. The patient also took strychnia and nitro-muriatic acid. Antipyrin, cannabis indica, and the bromides were not successful.

We have given the histories of these eight cases in which the results are sufficiently definite to stimulate further trial of this remedy. We are employing the drug in a number of cases, in which we are not yet in a position definitely to state the result; in others we know that relief has been afforded. Dr. Weir Mitchell and Dr. Wharton Sinkler, of the Infirmary staff, have employed the drug in like cases with benefit. The latter has used it in three cases with decided relief; in one, in a case of long-standing migraine, it was the sole medicine for five or six weeks. In this case the paroxysms, which were right supraorbital and severe, were materially shortened and the intervals lengthened.

Eucalyptus has been used with asserted success in migraine and other forms of neuralgia as mentioned above. In our experience it appears to be of most service in the headaches of congestive type; in one case where indiscretion in diet precipitated an attack the drug did not appear to be of use, although it relieved other seizures. In this and other of our cases the drug acted more beneficially when given at the very onset of the attack than after full development of the paroxysm, and we would suggest its trial as early as possible in the seizure, especially when there is a long prodromal period. The question has arisen, Are the headaches of a malarial origin that are relieved by this drug, or has it some other mode of action? In the first case the evidence of malaria is undoubted, in none of the other cases is it positive, and in some not at all probable. We intend, in a future paper, to give the results of further trial with the oil of eucalyptus, and hope to be able to state more definitely the type of headache in which the most relief may be anticipated. In two instances our results were entirely negative, in both an organic lesion existed, the one in the alimentary canal, the other in the ovaries. We have used the drug in one case of ciliary neuralgia without effect and intend to give it trial in other types of neuralgia.

COMPARATIVE RESULTS IN NINETY CASES OF PLEURISY, WITH SPECIAL REFERENCE TO THE DEVELOPMENT OF PHTHISIS PULMONALIS.[1]

BY VINCENT Y. BOWDITCH, M.D.,
OF BOSTON,
PRESIDENT OF THE AMERICAN CLIMATOLOGICAL ASSOCIATION.

HAVING watched for some time the various opinions and discussions upon the question of the tubercular nature of pleurisy and its subsequent development into phthisis, and being struck with the widely varying ideas upon the subject, it occurred to me to make an investigation as to the results of the cases of pleurisy occurring in my father's practice from 1849 to 1879.

While recognizing the impossibility in any such investigation of determining absolutely the tubercular or non-tubercular character of pleurisy, I believed that I might at least be able to draw some practical conclusions from the subsequent history of these cases which would assist us in giving advice to our patients, and, more especially, prevent us from unnecessarily alarming ourselves, our patients, and their friends: a tendency which, I think, needs to be constantly guarded against in our profession, in the practice of which we are continually subjected to the influence of extreme views founded upon theories unsubstantiated by facts.

It may be well here to mention some of the various opinions held by eminent men in different countries as to the nature of pleurisy.

The most extreme views are held by Landouzy, of the Paris Faculty of Medicine, who believes that nearly all cases of pleurisy are tubercular in character, and that the so-called simple pleurisy from "taking cold" is a very rare thing, but that the great majority are the expression of an incipient pulmonary tuberculosis which may appear at any subsequent time, even after an interval of many years. In this opinion he is enthusiastically followed by his pupils, J. R. G. Joanney[2] and Alois Mayor,[3] who give his views in two theses upon this subject.

Germain Sée[4] believes that three-fourths of all pleurisies are tubercular, and quotes Fiedler, who says that out of 112 pleurisies which were aspirated

[1] Read before the American Climatological Association, June 27, 1889.

[4] Sée (Germain). Boston Med. and Surg. Journal, March 11, 1886.

21 recovered, 25 died of phthisis, and 66 recovered from the pleurisy, but were found to be victims of other tubercular diseases.

Strümpell[1] speaks of the simple fibrinous or exudative pleurisy as a rare disease, and says that the larger proportion are tubercular, and claims that even if phthisis appears several years later it is probably the result of pleurisy, and that only in comparatively few do the symptoms of acute tuberculosis or chronic phthisis appear as an *immediate* result.

Among those who take more moderate views may be mentioned Chauvet[2] and Rühle,[3] who go only so far as to say that many cases of pleurisy are probably tubercular in character.

Demandre[4] speaks of the deformity of the chest and development of bronchiectasis, and says that usually with pleurisy comes an interstitial pneumonia, but gives no statistics as to the frequency of subsequent phthisis.

Gerhardt,[5] in 1879, speaks of pleurisy as often preceding phthisis, but also gives no statistics. Niemeyer[6] classifies various forms of pleurisy, and is evidently far from the opinion advanced by Landouzy.

Anstie[7] says: "It is now well established, not merely that pleurisy occurs in phthisis, but that pleurisy can set up true tuberculosis even in previously healthy persons."

Bartholow[8] speaks of the importance of recognizing pleurisy as a frequent cause of phthisis from causing tubercular deposit.

Loomis,[9] while recognizing the existence of tubercular pleurisy, is very far from believing that all cases are of tubercular nature, or that they will be followed by phthisis.

Sir Andrew Clark[10] recognized the fact that phthisis is by no means an infrequent sequence of pleurisy, but evidently is far from believing in the tubercular origin of all cases, and in these views he is supported by C. Theodore Williams,[11] who, in the second edition of his book on "Pulmonary Consumption," says on page 24: "Not uncommonly the friction sound of dry pleurisy in the supraclavicular region is the first sign of the presence of tubercle at the apex of the lung. . . . It is generally noted that the lungs are the first organs affected (in miliary tuberculosis), and it is extremely rare for tubercle to exist in any organ without also being present in the lung." On page 49 he says: "Chronic pleurisy, by crippling the movements of the lungs and thus promoting congestions and exudations, prevents the proper expansion of the alveoli, and thus affords a nidus for the bacillus;" and on page 271: "There are two principal modes of origin of fibrosis (that is, non-tubercular phthisis), firstly, *from attacks of pleurisy*, and pleuro-pneumonia, etc."

F. C. Shattuck,[1] in an article on pleurisy, for the *Reference Handbook of the Medical Sciences*, says: "Whatever views one may hold as to the frequency of primary effusion as an independent disease, it cannot be denied that recovery absolute and permanent is common enough;" and, further on, adds: "In view of the fact that tuberculosis does develop in cases of this class after an interval which may be long, we cannot regard them with quite the same equanimity as we are justified in preserving in cases where rational and physical signs alike disappear."

B. F. Westbrook[2] and Herman F. Vickery,[3] in papers published within the last two years, give results of cases of pleurisy which have subsequently become phthisical, and lay stress upon the importance of watching carefully the convalescence of pleurisies in all cases.

Strongly opposed to the views of Landouzy may be mentioned Theodore Dumin,[4] of Warsaw, who expresses the greatest astonishment at the former's conclusions, and claims that true tubercular pleurisy, where miliary tubercles begin on the pleura, is a rare disease. He believes, on the other hand, that most pleurisies are the result of pulmonary tubercle, which cannot be detected by physical signs, and that the prognosis of the latter form depends upon the course of the primary disease in the lung, which can be healed; views which seem to me as theoretical and difficult of proof as those he criticises.

A strong practical refutation of Landouzy's views appears in a paper by Blachez,[5] a man evidently of large practical experience, who scouts the idea of the tubercular origin of all pleurisies, and cites a

number of cases classed as simple pleurisy which have never in later years developed the least pulmonary trouble. He also makes special mention of an epidemic of "pleurésie à figore," which occurred in the army many years ago, the subjects of which he has kept under supervision since, not a single symptom of pulmonary trouble having appeared in any one of them.

E. Martel,[1] of Saint-Malo, comes to the same conclusion as Blachez, and regards as ridiculous the opinion that nearly every case of pleurisy is tuberculous.

Austin Flint,[2] in an analysis of 47 cases, states that in 3 the subsequent development of phthisis was probable, although not demonstrated, and in one case only was the occurrence of this disease as a sequel certain.

Of 53 cases reported by Blakiston,[3] not one became phthisical during several years after recovery from pleurisy.

Thus we have specimens of the widely varying opinions among different observers.

In obtaining my results I have addressed the following set of printed questions to the patients or their friends, answers having been frequently obtained from physicians, who have known the patients, or from town clerks:

1. Where have you been living since you consulted Dr. Bowditch?
2. What has been your occupation?
3. Has your general health since then been good, bad, or indifferent?
4. Have you been subject to cough since?
5. Have you had any lung trouble since, and if so, how long after you last saw Dr. Bowditch did the cough begin?

Should the patient be no longer living, will the friends kindly answer the following questions?

1. How long after the patient saw Dr. Bowditch did he (or she) die?
2. What was the cause of death?
3. Did the patient recover entirely for any length of time after last consulting Dr. Bowditch?
4. Was he (or she) subject to cough?
5. If lung trouble caused the death, about how long after seeing Dr. Bowditch did the cough begin?

If any reputable physician saw the patient at any time, please give his name and address; and if the physician has removed or died, please state, if you can, what he thought the patient died of.

Although the number of cases in which I have been able to collect satisfactory data is small in comparison to the number addressed, yet considering the lapse of time and the frequent uncertainty of address, I am gratified at having received replies from so many.

In analyzing the cases I have attempted no distinct classification into so-called "dry pleurisies," pleurisies with serous effusion and empyemas, but have put them all together, my endeavor having been to cast out every case in which there was the least evidence, upon careful examination, of coexisting pulmonary disease (for we all know that pleurisy is a frequent accompaniment of phthisical trouble).

Le me say, also, that with our knowledge that tubercular disease can arise and be checked never to reappear, I should not be so foolishly illogical as to attempt to prove in any given case of pleurisy that because of the subsequent health of the patient it was, therefore, of non-tubercular character. It would, moreover, be a just criticism to speak of the possibility of preëxisting disease of the lung in some of the cases mentioned, even when the most careful examination failed to reveal any such condition.

Any such possible error is only an example of the extreme difficulty of arriving at precise conclusions in such questions.

My aim, therefore, is simply to show, as far as possible, how many of the patients have regained and kept their health and how many have succumbed later to phthisis or other probably tubercular disease.

For the sake of convenience, I have divided the thirty years from 1849 to 1879 into decades.

During the first decade, from 1849 to 1859 inclusive, I have the records of 30 patients.

Of these, 11 are now (1889) living, and have all been well, except one who has been subject to cough since at times; 17 are dead. In 2 the condition today is not known, although in one case phthisical symptoms developed fourteen years after the examination, and is classed accordingly; and the other, seven years after the first illness, showed "perfect percussion note and respiration everywhere."

Of the 17 who died, 12 died of phthisis; 5 died from other causes:

No. 1, of chronic rheumatism thirty-five years later, aged eighty-five.

No. 12, from suicide during melancholia twenty-five years later, aged thirty, in the interval having been in robust health.

No. 14, from angina pectoris five years later aged fifty-eight, having been well in the interval.

No. 16, from "acute gastritis" thirty-one years later, aged sixty-nine, no evidence of pulmonary trouble showing itself, although rather delicate.

No. 3, from "inflammation of the bowels" twenty-two years later, aged forty-one, no apparent pulmonary trouble having been present, although after great privations in army life a cough appeared for some time, and then disappeared entirely.

Adding to the number now living, 11, the 1 whose present condition is unknown, but who seven years after the first examination showed a perfectly normal condition, we have 12 who recovered entirely, or 40 per cent.

[1] Martel (E.): Gaz. Heb. de Méd., 1886, 2 s. xxiii. p. 699.
[2] Flint (Austin): Pepper's Hand-book of Medicine, p. 394.
[3] Blakiston: Ditto.

Adding to those who died of phthisis, 12, the 1 who developed phthisis fourteen years after the first examination, we have 13, or 43⅓ per cent.

Died from other causes, 5, or 16⅔ per cent.

In the second decade, from 1860 to 1869 inclusive, I have records of 19 cases.

Of these, 7 are now living, 5 having been in robust health since, 2 somewhat delicate, but without apparent pulmonary trouble.

12 are dead: 9 have died of phthisis, or have developed symptoms since; 3 have died from other causes. One (No. 32) died from "intermittent fever and chronic diarrhœa contracted in the army" two years later, aged thirty (questionable tubercular trouble). No. 40 died of acute mania twenty-three years later, aged thirty, the intervening period having been one of robust health.

Living = 7, or 36 + per cent.

Dead from phthisis, or with phthisical symptoms now = 9, or 47 + per cent.

Dead from other causes = 3, or 16 + per cent

Of No. 32 it should in fairness be noticed that the question of tubercular trouble in the intestines is raised. If such was the case, the original pleurisy was very possibly tubercular, which would alter the percentage slightly.

In the third decade, from 1870 to 1879 inclusive, I have the records of 41 cases.

Of these, 25 are now living without pulmonary symptoms, of whom 23 have been in good health since; 2 are not robust.

15 are dead: 9 have died from phthisis, and 1 (No. 87) is now phthisical = 10 phthisical; 6 have died from other causes: 3 (Nos. 51, 53, and 61) from heart disease, all over fifty years of age, and from ten to fifteen years after examination; 1 (No. 67) from apoplexy following Bright's disease twelve years later, aged sixty-eight, with apparently perfect health in the interval; 1 (No. 72) from "intestinal obstruction" eleven years later, aged fifty-one, perfectly well before; 1 (No. 76) from "paralysis" three years later, aged fifty-one.

Living without pulmonary symptoms, 25 = 61 + per cent.

Dead from phthisis, or now having symptoms of phthisis, 10 = 24 + per cent.

Dead from other causes, 6 = 14 + per cent.

In comparing the percentage of mortality from phthisis in the cases from 1870 to 1879 inclusive with that of the cases of the first decade, 1849 to 1859, we find the percentage 24 per cent. in the former as against 43⅓ per cent. in the latter, and against 47 + per cent. in the second decade, from 1860 to 1869 inclusive.

In attempting to explain this difference in percentage we must not lose sight of the fact of the possibility of the development of phthisical symptoms later in those of the third decade who now seem perfectly well. In one case reported by Mayor phthisical symptoms did not appear until twenty-four years after the pleuritic attack which occurred during childhood, this being, so far as we know, the longest interval spoken of, the patient, a comparatively young woman, succumbing to pulmonary disease—whether a result, as Mayor would have us believe, of the previous pleurisy, or not, being to my mind most questionable.

The fact remains that long periods of perfect health do occur between the onset of the two diseases, and we must, therefore, take this into account in comparing the later with the earlier decades.

In looking carefully over the tabulations, I find, in the first decade, among the deaths from phthisis, the following points:

1 patient died eighteen years after the pleuritic attack.

3 patients died between ten and fifteen years after the pleuritic attack.

9 patients died in seven years or less after the pleuritic attack.

In the second decade, 1860 to 1869 inclusive:

1 patient died in eighteen years after the pleuritic attack.

2 patients died between ten and fifteen years after the pleuritic attack.

6 patients died under five years after the pleuritic attack.

In the third decade, from 1870 to 1879 inclusive:

1 patient died eleven years after the pleuritic attack.

1 patient died ten years after the pleuritic attack.

7 patients died under seven years after the pleuritic attack.

1 patient, still alive, developed phthisical signs about ten years later than the pleuritic attack.

Thus we see that in the first two decades about two-thirds of those who died of phthisis succumbed in seven years, or less, while about one-third lived from ten to eighteen years after. If we adopt the same ratio for the third decade, we have already passed the period (ten years) during which two-thirds of those who developed phthisis succumbed, and even supposing the possibility of a later appearance of phthisis in the remaining one-third, it still leaves the percentage of mortality from pulmonary disease from ten to fifteen per cent. less than in the previous decades.

Should this result be found similar to others in the future, it would give us ground for believing that modern methods of treatment in these cases are productive of better results than in the past. While not attempting to prove this fact, of course, by such tabulations, and granting that it may be mere coincidence, it is at least worthy of remark,

and certainly points favorably toward the greater attention paid in later years to the after-treatment of pleurisies, by proper expansion of the chest, outdoor exercise, good food, etc.

In connection with the preceding, and as opposed to the extreme views mentioned before, I wish before closing to lay special stress upon this point, viz., that I consider as most unwarrantable the assertion, that because phthisis develops in any subject who, several years before, has had pleurisy, the two diseases in every case are necessarily dependent upon each other, the intervening period having been one of robust health.

As an example, let me cite the following case:

A man, now thirty-eight years of age, eleven years ago developed a sudden acute pleurisy, with effusion on the right side, for which he was aspirated by my father, after which he recovered quickly, but three months later was attacked with similar symptoms on the left side, for which he entered the City Hospital, where the fluid gradually disappeared without aspiration. In a few months he entirely regained his health, and has been perfectly well ever since, pursuing his occupation as conductor on one of the railroads near Boston. I examined him this spring, and found him a man of robust health, of good color, the chest full and well formed, the percussion and auscultation on both sides absolutely perfect without a trace of his former pleuritic trouble.

Now even supposing the possibility of a subsequent development of phthisis in this man, should we be justified in saying that the double-sided pleurisy was the first sign of the pulmonary disease which appears in later years? Most assuredly not, it seems to me; on the other hand, why is it not perfectly possible in such cases that the subsequent pulmonary disease is an independent process arising in precisely the same way as in other cases in which no history of a former pleurisy can be obtained?

This and similar cases where there is a long period of perfect health, make me think that the advocates of the certain connection between the two diseases and of the tubercular nature of all pleurisies are drawing conclusions too hastily.

The results of this investigation show us at least:

First. That whether we can prove absolutely, by such statistics, that all pleurisies are tubercular or not, yet a large percentage of these patients who were afflicted with pleurisy, often in apparently chronic forms, recovered their health and have never had any recurrence of the original trouble nor development of subsequent pulmonary or otherwise tubercular trouble.

Second. That while undoubtedly there are many cases in which an attack of pleurisy is followed within a comparatively short space of time by pulmonary trouble; and, therefore, special care should be taken of the patient during convalescence from the former disease, yet we are not justified in giving such gloomy prognosis as we should be inclined by accepting the extreme views held by Landouzy and his followers.

To give hope and courage to patient and friends should be the first effort of every physician.

Let us be doubly on our guard then, while looking for the truth, in accepting conclusions founded upon insufficient evidence, lest we run the risk of hindering what we most desire, viz., the recovery of our patients.

REPORT OF TWENTY-FOUR CASES OF ACUTE MILIARY TUBERCULOSIS.[1]

BY JOHN C. MUNRO, M D.,
OF BOSTON.

THE following analysis of twenty-four cases of acute miliary tuberculosis of the lungs has been made in order to furnish, if possible, some clews toward the detection of a disease that not infrequently bewilders the most careful practitioner. The cases have been taken from the records of the Boston City Hospital, and it is to the courtesy of the members of the staff that I owe the pleasure of presenting this brief consideration. For the use of some valuable private notes made on a number of the patients by Dr. Samuel Delano I feel greatly indebted also.

All the cases were fatal, occurring within the last five years, and only those in which a post-mortem examination was made have been chosen.

The number is too small to attempt to draw percentage conclusions, and some factors, generally considered of importance, have been passed over because of insufficient data.

Fourteen patients were males, with an average age of thirty-eight years, that of the females (not including one child two and a half years old) being only thirty-two years. The oldest, a man, was sixty-five years of age, while eight were between the ages of forty and sixty years. Over half were born on or near our eastern coast; two were negroes.

The majority were ill in February, March, or April; their occupations were of various kinds and apparently had no causative influence.

Only three gave a phthisical family history; in twelve it was not phthisical, while in nine no history could be obtained.

Three-fourths of all the patients had always been well up to the time of the present illness, and although in thirteen cases the autopsy revealed a chronic tuberculosis in addition to the acute miliary process, yet of this group only a single patient had given a history of having suffered from phthisis; in fact, the remainder had always been looked upon as healthy. Even though there was a history of cough for one or

[1] Read before the American Climatological Association, June 24, 1889.

more months in quite two-thirds of the cases, it was noted as being slight, with a muco-purulent expectoration and had excited no alarm except in one instance where several attacks of profuse hæmoptysis had occurred. Severe cough was recorded in two cases, but in each it had begun less than a month before admission to the hospital.

Among the exciting causes might be mentioned the following: overwork and exposure in a damp cellar; several weeks of hard drinking, with but little food; partial asphyxiation from drowning; measles, scarlatina, whooping-cough with measles, and vaccination each in one case.

The clinical diagnoses varied considerably, from tubercular meningitis in eight cases, to exhaustion, typhoid, bronchitis, etc. Two patients died immediately after admission to the hospital, so that very little history and no physical examination could be obtained.

About one-third of the cases gave a clear history of a marked chill ushering in the disease; a few more complained of feverishness and malaise, while headache, naturally frequent in those with a meningeal affection, was pronounced in a few others.

Loss of flesh, strength, and appetite, wherever noted, came on rapidly and was very marked. Likewise night-sweats, though recorded too few times to be of much value, were always profuse.

In one-half of those cases where derangement of the menstrual function could serve as an indication of any general trouble no record is made, but in the other half all the patients had had amenorrhœa for from one to four periods.

In the two cases that had had hæmoptysis an old cavity was found in the lungs at autopsy.

The condition of the bowels gave no light in making a diagnosis; cases with tuberculous ulceration of the intestines were apparently affected neither one way nor the other by the lesion.

The tongue was generally coated and dry; in a few cases cracked.

The temperature in a majority of the cases at entrance was 100° F. or over, the pulse 100 or over, and the respiration 28 or over; of the course of each throughout the disease mention will be made later.

In seventeen cases an examination of the urine was made, and albumin, generally a slight trace in amount, was found in eleven. Of the latter, autopsy showed an acute tuberculosis of the kidneys in over seventy per cent., whereas of the six cases in which albumin was not found, only three (fifty per cent.) had a similar lesion. Notwithstanding these numbers are too small to warrant definite conclusions, they at least suggest that there may be some connection between the two conditions.

The eyes were examined in four patients; one, with sarcoma of the hypophysis had atrophy of both disks; two had a double optic neuritis, and, finally, one had tubercle of the choroid. Considering the importance that some writers attach to this latter condition, it is unfortunate that more cases were not examined with the ophthalmoscope.

Examination of the heart afforded no assistance in diagnosis so far as the recorded results show.

The signs obtained from careful physical examinations of the lungs, though often confusing and misleading, apparently show an undercurrent of certain definite characteristics. The disease is of such a nature, and the lungs are so frequently the seat of some other morbid process that only examinations most carefully made during life, and compared topographically with the lesions found after death, can establish what signs belong properly to an acute miliary infiltration. A few cases carefully studied in this way would help wonderfully to clear up certain obscure points. Unfortunately, from the predominance of some symptom, or set of symptoms, pointing elsewhere than to the chest, the lungs are not infrequently hastily examined merely to exclude a more definite lesion, like lobar pneumonia, and are not again considered during the course of the disease. However, in the present group of cases certain characteristics seemed present so far as could be learned from the recorded examinations, many of which were very carefully and thoroughly made.

In the cases where there was a chronic in addition to the acute tuberculous process—that is, in the acute-chronic cases, percussion showed that dulness was not necessarily confined to the region of chronic infiltration, but might be extended to a considerable distance beyond, and be repeated in some other area where no chronic process existed. In a few simple acute cases where no dulness is recorded, it was probably overlooked; in the remainder it varied from a feeling of lessened elasticity to a moderate degree of dulness in localized regions over a single lobe or even over an entire lung.

In nearly every case where fremitus or vocal resonance was increased, the effect of a chronic induration could not be ruled out.

The respiratory murmur in simple acute cases was, for the most part, indistinct, harsh, with a high-pitched inspiration and a lower-pitched, prolonged expiration. In acute-chronic cases all qualities are recorded, but in the majority it was feeble in intensity, harsh, with high-pitched inspiration, and a prolonged expiration grading from a lower pitch to a bronchial quality.

The râles heard in simple acute cases were almost invariably few in number, fine in quality, dry, and sometimes moist, high-pitched, and less often low-pitched (none of the latter being moist). Often several kinds were to be heard in the same patient. In acute-chronic cases they were coarser in type,

more numerous, and more moist, besides being accompanied by those of a fine dry or a fine moist character. In one or two cases, even with a chronic process, only a few râles of any kind were recorded.

The clinical history of the cases while under treatment can be briefly summarized. They rapidly lost strength and flesh, delirium or coma soon appearing in nearly every case. The pulse steadily increased in frequency and decreased in strength. The respiration, somewhat rapid at entrance, increased in frequency, becoming more and more shallow, and often irregular with increasing cyanosis. A few developed abdominal tympanites; a few, pain in the chest. Even though in several cases a slight amelioration intervened for a few days, the course was steadily and rapidly down-hill to death, and no treatment seemed to be of any avail in checking its progress.

The clinical charts showed nothing very significant, except, perhaps, from a negative point of view. The temperature ranged from 101° to 103° F., on the average, making daily excursions of one or two degrees, while very rarely was it higher in the morning than at evening; it seldom fell below the 100° line, and rarely rose as high as 104°. The pulse rarely fell below 100, and often rose to 140 beats or more; its line steadily ascended while the daily excursions were not very marked. The line of respiration followed very closely that of the pulse, both frequently being high without any corresponding elevation of temperature. In no case was there cessation of fever before death.

The duration of the fatal illness, reckoning from the initial chill or other marked symptom, averaged thirty days; in uncomplicated acute cases, where the beginning could be more accurately determined, the duration was shorter by about four days. The average length of stay in the hospital, excluding the two cases that died at entrance and one previously under treatment for measles, was fifteen days, so that they were all well developed before any systematic treatment had been undertaken.

The following complications of cases while in the hospital are important: One woman, fifty-eight years old, had sarcoma of the hypophysis with a few cerebral symptoms; one, supposing herself pregnant, had just attempted abortion, and during her stay was attacked with facial erysipelas; one man had general psoriasis, and one had probably an acute tubercular pleuritis.

The post-mortem examination in every case showed an acute miliary tuberculosis of the lungs, and, so far as could be judged, it was the important, or one of the important, pathological conditions. As mentioned before, thirteen showed in addition some degree of chronic tuberculous process going on, often with cavity formation. Where a focus for general infection did not exist in the lungs themselves, one could always be found in one or more groups of lymphatic glands. In thirteen cases, divided almost equally between the acute and acute-chronic, there was an acute tuberculosis of the meninges, causing so marked symptoms during life that the diagnosis was strongly influenced. Next to the lungs, the following organs were invaded by tubercles: the spleen in 15 cases, the kidneys in 14, the meninges in 13, various groups of lymphatic glands in 11, the intestines (with ulceration) in 10, the liver in 9, the pleura in 7, the pericardium and peritoneum each in 3, the bladder, diaphragm, and a supra-renal capsule, each in 1.

In conclusion, these cases would seem to indicate that an acute pulmonary tuberculosis should be suspected when the following indices are present (the existence of other pathological conditions in the lungs giving rise to characteristic signs and symptoms that ought not entirely mask those under consideration): Sudden severe illness, ushered in with a chill, in a person previously healthy or with a history of chronic phthisis; slight cough and expectoration, no hæmoptysis, marked loss of flesh and strength; loss of elasticity, or a slight dulness over part or the whole of a lung or surrounding a limited area of marked dulness; indistinct, harsh respiration, with high-pitched inspiration and prolonged low-pitched expiration; a few scattered fine dry or fine moist râles, generally high-pitched; a rapid, weak pulse, with quickened, shallow respiration, and cyanosis out of proportion to the physical signs; a temperature steadily feverish, but without marked variations; local evidences of miliary infiltration in other organs.

MEDICAL PROGRESS.

The Channel of Tuberculous Infection.—Another piece of work emanating from Dr. Koch's Hygienic Institute, was an address by Dr. Cornet on the channel of tuberculous infection, which is referred to in the Berlin letter to the *London Medical Press* of June 12th.

The knowledge that infection in cases of pulmonary phthisis took place generally through particles of dried sputum reaching the lungs was important from a prophylactic point of view, as the speaker pointed out, and if we could determine the point of entry of the virus in glandular tubercle also, our aim would be more intelligent and precise. The speaker's attention was first directed to the cervical submaxillary and occipital regions. He showed some guinea-pigs into whose conjunctival sacs some sputum containing tubercle bacilli had been placed. No injury of the sac took place. Notwithstanding this, the bacilli grew, penetrated the tissues, and set up swelling and hyperplasia of the conjunctiva. In all the animals caseation and softening subsequently took place in the neighboring glands. The side on which the inoculation took place showed the most extensive changes. In two other animals the nasal

mucous membrane was painted by means of a pigeon's feather, with bacillary sputum in one case, and a pure cultivation of tubercle bacilli in the other. The corresponding glands became tuberculous in both cases. In other cases the cavity of the mouth was inoculated with sputum or pure cultivation material, and all the corresponding glands became tuberculous. In another guinea-pig infective material was introduced into the ear, and the auricular glands became subsequently caseous. In still another animal the skin over the nose was shaved clean and sputum rubbed in, when later on a serpiginous ulceration covered with a thick scab, reminding one of lupus, was observed; the cervical glands became much enlarged. Another animal was scratched on both cheeks with a finger-nail dipped into tuberculous sputum, and the ulceration, covered with scab, that followed, spread and became confluent. Another animal was rubbed, but without abrading the surface, with a wash leather that had been dipped into bacillary sputum; after some weeks it was killed, when the corresponding lymph-glands were found enlarged. Other animals again were infected from the vagina, penis, toes, etc. He concluded that tubercle bacilli could penetrate into the system without causing distinguishable injury at the point of entry. The nearest lying glands became tuberculous and illness developed resembling scrofula as it was often seen, and without doubt scrofula depended on a tuberculous infection from without. This was the less remarkable when we remembered how incautiously we treated phthisical sputum, and how frequently children made a way for the entrance of disease by putting every possible object within their reach, covered with tuberculous dust it might be, into their mouths, up their noses, or into their ears.

Capillary Bronchitis in Children.—The necessity for active treatment in cases of capillary bronchitis occurring in young children or infants, is readily recognized. DR. JULES SIMON, in an article on this subject (*L'Abeille Médical*, June 3, 1889), deals at length with the most efficient methods used in treating this disease. The therapeutic measures which he has found most useful are, briefly outlined, as follows: The child should be at once put to bed and well wrapped up; large sinapisms should be placed on the chest, and a teaspoonful (or less, according to age) of the following mixture should be given every hour:

℞.—Gum mixture	f ℥iijss.
Alcoholic extact of aconite (Fr. P.)	gtt. xv.
Acetate of ammonium . .	gr. xv.
Syrup of codeine , . .	℥jss to ℥jv.—M.

If necessary, the child should be put in a sinapic bath for about five minutes, and afterward well dried and wrapped in hot blankets. The bath may be repeated at intervals without danger. Stimulants should be given in the form of champagne, egg-nogg, or toddies. If the nervous system has suffered greatly, the following injection may be resorted to:

℞.—Hydrate of chloral . .	grs. vij to xv.
Water	f ℥ij.
Tincture of musk . .	gtt. xx.
Tincture of valerian . .	gtt. xv.—M.

Quinine will be found most valuable during the entire course of the disease. It is usually administered in doses of from one to two and a half grains, and is best given in the form of a potion in glycerine, with the addition of a little tartrate syrup.

Massage in Chronic Typhlitis and Perityphlitis. — DR. GEORGE HÜNEFAUTH, in an exhaustive article on the subject of massage in chronic typhlitis and perityphlitis, cites fifty-three cases in which the treatment was followed by complete cure. Hot applications to the abdomen were also found valuable, as well as a mild course of water treatment, consisting of rubbing down with cold water, douches, and hip-baths. These have always exerted a beneficial action upon the appetite and sleep. The treatment, which should take place twice daily, and should last for about fifteen minutes, should be continued for three to four months. In mild cases, six or eight weeks will often effect a cure.—*Münch. med. Wochen.*, May 28, 1889.

An Antiseptic Solution.—Under the title of "An Ideal Antiseptic," DR. ROTTER, in the June number of the *Gazette de Gynêc.*, gives the following formula:

Corrosive sublimate . . .		5 parts.
Chloride of sodium . . .		25 "
Phenic acid		200 "
Chloride of zince Sulphocarbonate of zinc	āā	500 "
Boric acid		300 "
Salicylic acid		60 "
Thymol Citric acid	āā	10 "
Water		100,000 " —M.

If a weak solution be required, the sublimate and the phenic acid may be omitted. The above solution will not injure instruments.

The Treatment of Dysentery with Creolin.—After having carefully observed the effects of creolin in sixteen cases of dysentery, DR. OSSOVSKI, in the *Revue gén. de clin. et de Thérap.*, June 6, 1889, unhesitatingly recommends it in this disease. The treatment followed by him was merely to give the patient two to four large injections daily of a solution of creolin (1 to 100). Besides its antiseptic properties the drug also acted as a hemostatic, and quickly checked the bleeding of the irritated intestine. When given to patients subject to malaria, the drug in some instances caused a rise of temperature, which, however, was speedily overcome by quinine.

Exalgin in Dysmenorrhœa.—Exalgin is fast being introduced into the therapeutics of various ailments. Its most recent successful use is, perhaps, in neuralgic dysmenorrhœa, in which painful affection its anodyne properties give most satisfactory results. The following formulæ for its use are quoted from the *Revue de Thér. méd.-Chir.*, June 1, 1889:

℞.—Curaçao	f ℥jss.
Exalgin	grs. xl.—M.

A teaspoonful of the above contains about four grains of exalgin. Curaçao is the best medium for its ad-

ministration, as it almost completely disguises the unpleasant taste of the drug. Another agreeable formula is:

℞.—Linden-flower water . . . 100 parts.
Laurel water . . . . 10 "
Curaçoa . . . . . 40 "
Exalgin . . . . . 3 " —M.

Sig. A seaspoonful to be taken every half hour until the pain ceases. Doses of a dessertspoonful may be given if the pain is very intense.

Fracture of the Thyroid and Cricoid Cartilages; Recovery.—An interesting and rare case, reported in the *Lancet* of June 8, 1889, was recently exhibited by DR. SOKOLOVSKI at the Warsaw Medical Society, of a woman in whom the anterior portion of the thyroid and both halves of the cricoid had been fractured through an accident with the strap of a mill. The immediate symptoms were severe pain in the throat, cough, and the expectoration of a considerable quantity of blood, also marked dyspnœa. Tracheotomy (inferior) was performed the second day. During the fourth week portions of the necrosed cartilage came away. After two months both halves of the thyroid were removed with forceps, and it was found that no trace of the cricoid remained, the posterior wall of the glottis being formed by the anterior mucous coat of the œsophagus. The patient made a good recovery, and was soon able to swallow food without difficulty. It is noteworthy that the condition of the larynx was accurately ascertained on the second day after the accident by means of the laryngoscope, and also that cases of fracture of the cricoid are almost invariably fatal.

Cocaine Poisoning.—From the large number of cases of cocaine poisoning which have been reported, it is evident that in different individuals the susceptibility of the drug is very different; indeed, this is the case in the majority of instances. This fact calls for the greatest caution in the use of the drug.

Probably the toxic symptoms which have been observed are due to an irritation of the sympathetic nerve, as dizziness, coldness of the extremities, perspiration, enlargement of the pupils, and a quickening as well as weakening of the heart's action are always observed.

The treatment of severe cases of poisoning, when accompanied with marked symptoms of collapse, must be the active use of stimulants; in cases of severe muscular movements unaccompanied by loss of consciousness, narcotics will be found valuable. Some authorities claim to have observed beneficial effects from inhalation of nitrite of amyl. From numerous experiments upon animals RICHET and LANGLOIS have discovered that the toxic action of cocaine is greater when the animal is subjected to a high temperature, and steadily increases with the rise of temperature. When a dog, into which a minimal quantity of cocaine had been injected, was placed in a bath of a temperature of 107° F., it was immediately seized with convulsions. The same animal was able to endure, without toxic symptoms, an injection fifteen times as large as the preceding one, when placed in a bath of a temperature of 87° F. Cold baths or applications would, therefore, constitute a most rational therapeutic agent in cases of cocaine poisoning in man.

We quote two recent cases of cocaine poisoning which are of special interest. The first is reported by DR. HÄNEL in the *Berliner klinische Wochenschr.* A dentist injected $1\frac{7}{10}$ grains of cocaine into the gum of a strong, although somewhat chlorotic, nineteen year old girl, prior to the extraction of a tooth. The above quantity he divided into two injections. Immediately after the second injection the patient became pale and fell into strong convulsions. Nitrite of amyl had no effect. When Hänel saw the patient she was entirely insensible, slightly cyanosed, and in severe convulsions which lasted for five hours. The pupils were greatly enlarged and showed no reaction; pulse at first impossible to count, later 176; respiration 44. The temperature in the axilla at the end of this stage was 101° F. After the convulsions had ceased the patient lay unconscious for two hours and upon awakening evinced a strong photophobia. The skin was slightly anæsthetized, the mouth, throat, and nasal cavity totally so. Other symptoms were thirst, retching, retention of urine, lasting twenty-four hours; sleeplessness for thirty hours, and total loss of appetite. All the symptoms above named, with the exception of the last, disappeared within two days. Hänel is of the opinion that the maximum dose of cocaine should not exceed half a grain, and that in patients with cardiac weaknesses even this dose is inadvisable.

The second case, which is reported by DR. MOIZARD in the *Centralbl. für Chirurg.*, June 1, differs from others in that the drug was taken by the mouth, whilst in the majority of poisoning cases recorded the drug has been administered hypodermically into the mucous membrane. Nearly four grains of cocaine in solution were given by mistake to a child aged four. The symptoms manifested were muscular twitchings, convulsions, nystagmus, extreme nervousness without loss of consciousness. These lasted for several hours. The next day there were still slight muscular twitchings which, however, ceased in thirty-one hours. The therapeutics employed were primarily emetics and subsequently cathartics.

Morphine-Vaseline as a Local Application in Cancer.—According to DR. B. W. RICHARDSON, morphine combined with vaseline forms one of the best possible sedative applications in cases of external malignant disease in which there is ulcerative breach of surface with continuous pain. The mode of prescribing the preparation runs as follows:

℞.—Vaseline, pure . . . . ℥j.
Chloroform . . . . . ℥ij.
Morphine . . . . . gr. iv.
Mix thoroughly and make into an ointment.

By using the chloroform a larger quantity of morphine can be introduced than if the alkaloid were used alone, the distribution through the mass being more complete. The chloroform, in the proportions named, causes, as a rule, no irritation, but acts rather as a sedative. Chloroform also is a powerful antiseptic, and as such is a good remedy in the class of cases under consideration.

Morphine-vaseline is most conveniently applied thinly spread over a piece of fine lint or soft linen. It is easily removable without injury to the surface upon which it is applied, and it may, therefore, be used even on surfaces from which the danger of hemorrhage is foreseen. The dressing may be renewed twice in the course of twenty-four hours.—*The Asclepiad*, 2d Quarter, 1889.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

PHILADELPHIA.

SATURDAY, JULY 20, 1889.

A TYPHOID EPIDEMIC FROM POLLUTED WATER.

THE annual report of the Superintendent of Health, of Providence, R. I., for 1888, contains an account of an epidemic of typhoid fever extending through the months of November and December of that year, which embodies several features of more than ordinary interest. In searching for the cause of the outbreak suspicion pointed to the water-supply as being most likely at fault. Accordingly, an inspection was made of the valley of the Pawtuxet, the river which furnishes the water-supply of Providence. The result was the discovery of contamination of the river water by typhoid excrement discharged into it at the village of Natick, about three and one-half miles above the pumping-station. Biological investigations of the water-supply of the city were immediately instituted with the object of discovering the particular organism of typhoid fever, but with only negative results. The failure is not surprising, as the detection of this particular species in a body of water whose daily flow is many millions of gallons is a task of extreme difficulty.

During the epidemic a large number of patients were found who had used water which had been passed through ordinary domestic filters, and it was determined to examine some of these filters in order to learn whether or not they contained the specific organism. The filters were obtained from houses in which there were cases of true typhoid fever, and care was taken to select only those in which there was no chance of contamination except from the water which passed through them. The bacteriological examinations were made by Dr. Swarts, the medical inspector, Dr. Prudden, of New York, and Dr. Ernst, of Harvard, all skilled bacteriologists. Besides the typhoid bacilli, several organisms characteristic of fecal matter were found in the filters, indicating the source of specific contamination. The results of the investigation seem to warrant the conclusion that the epidemic was due to the pollution of the Pawtuxet River by the excrement from typhoid fever patients. It is to be regretted that a comparison was not made between the number of cases of fever among persons who had used filtered water and those who had used water direct from the faucet.

The report incidently illustrates the inefficiency of domestic filtration. There can be no doubt that filters of the ordinary kind, composed of gravel, sand, and charcoal, and similar media, favor the development of bacteria. The results of the experiments of Dr. Currier, recently published in THE NEWS, show conclusively that filters, after continued use, yield water teeming with bacteria, although the unfiltered water may contain only a small number of these minute forms of life. Even the porcelain and stone filters, which are by far the most efficient, need to be sterilized at brief intervals in order to maintain satisfactory action. When water contains only harmless bacteria this special defect in filters is of little consequence; but when, perchance, the specific organism is present, the filter becomes a culture-bed for the multiplication of germ-life which is capable of infecting the water passing through it for an indefinite length of time.

Domestic filtration, unless conducted under scientific oversight, which is impracticable, apparently tends to increase the danger from the use of water containing infectious matter, and is therefore unreliable. The perfection of house-filters according to the germ-test is a most difficult problem. Even when the question is solved, the fact remains that these aids to purification are used by only a small proportion of the population. When, therefore, water is sufficiently impure to require filtration, it is most advantageous to have the process carefully conducted on a large scale at the public works.

It is a false civic economy and reprehensible administrative policy that dallies with a doubtful or positively bad water supply, and burdens the individual with expedients for protecting himself from

the possibly injurious effects from its use. The purest and best possible water should be obtained at whatever expense, and the supply carefully protected from contamination, and, if necessary, the most reliable means of artificial purification employed. When this is accomplished domestic filtration will be unnecessary.

The connection between typhoid fever and drinking water contaminated by excremental matter of specific quality as a cause, has been well established. It has also been ascertained that filters, such as are in common use, do not remove the infectious matter from water thus contaminated. When, therefore, there is real danger of infection, filtration may be employed to remove sediment or cloudiness, but the only safety lies in finally boiling the water.

CAFFEINE IN MIGRAINE.

DR. E. J. OVEREND, of Oakland, writes in the *Pacific Medical Journal* regarding his personal experience with caffeine in sick-headache. Having himself been a victim for many years, he has had an ample opportunity to test the comparative values of many drugs, from the study of which he rises with the conviction that caffeine comes as near being a specific in migraine as does quinine in intermittent fever. He is even inclined to rate its claims to specificity beyond those of the latter, but like that drug its prophylactic power outranks its curative value. His practice is to anticipate the attack by doses of two to five grains hourly, dispensed in capsules; this seldom fails to abort the attack if taken sufficiently early, or if not so taken, a marked amelioration of the symptoms results. He counsels his patients not to procrastinate, as they are prone to do, but to begin promptly the dosage as soon as the well-recognized prodromes appear. When capsules are objectionable to the patient and a solution is preferred, the salicylate of sodium should be combined with the citrate of caffeine, his belief being that the former salt not only renders the latter more stable, but also acts as a synergist. If recently reported experiments are correct, caffeine has another noteworthy advantage in that it does not enslave as do some of the narcotic remedies that are used in this affection. He has not found it necessary to increase the dose progressively, as is commonly the case with the habit-forming drugs.

Of the various proprietary preparations containing caffeine he has no commendatory evidence to give; they contain too little caffeine and too many unnecessary adjuncts, and of the effervescent compounds he remarks that they seem to contain more "fiz" than caffeine, and they give him the impression that cheapness plays a part in their construction. Dr. Overend's paper is written in a scholarly and sympathetic vein and we recommend it to the many medical men who are victims to migraine as a useful bit of post-graduate instruction.

As a result of the introduction of a supply of pure water from the Höllengebirge, in 1874, the death-rate of Vienna has fallen from 35.2 to 25.3 per 1000. The deaths from typhoid fever alone up to 1874 amounted to 700 each year. Since that time the number of deaths from this disease has fallen to 169 per annum. But Vienna has outgrown the capacity of the Höllengebirge to meet its wants, and a portion of the supply has been derived from the Potschach and also from the Schwarza Canal, the latter source being of doubtful quality. The recurrence of typhoid fever the past winter, coincident with the use of this suspicious water, has excited public comment, and plans are already being considered for supplementing the supply from greater and more distant altitudes. The beneficial effects of an improved water-supply have been so plainly demonstrated by practical experience that the Viennese municipality has been warned that no relaxation of its efforts on behalf of the public health will be tolerated.

DR. J. SOLIS COHEN, of Philadelphia, was elected, at its last meeting, an Honorary Fellow of the British Laryngological and Rhinological Association.

THE Tenth International Medical Congress will be held at Berlin on August 4 to 9, 1890. A general meeting of representatives of all the medical faculties and societies in Germany has been called by Professors Virchow, von Bergmann, and Waldeyer for September 17, to discuss the arrangements to be made for the Congress. Among those expected to be present at this conference, it is stated, are all the men of light and leading in the medical profession in Germany.

THE Seventh Special Meeting of the Fifth District Branch of the New York State Medical Association, will be held in Port Jervis (Orange Co.) N. Y., on Tuesday, August 27, 1889, under the presi-

dency of Dr. W. T. Lusk, of New York. For those who are willing to spare the time after the meeting, a beautiful and interesting carriage drive of seven miles along the Delaware River to Milford, Pa. is promised. The Committee of Arrangements, of which Dr. J. H. Hart, of Orange Co., is Chairman, is making every preparation to insure an interesting meeting, both scientifically and socially.

The Twentieth Annual Session of the Medical Society of Virginia will convene at Roanoke, on Tuesday, September 3d, at 8 P. M., under the presidency of Dr. E. W. Row, of Orange.

At the annual commencement of the medical department of the University of Vermont, held at Burlington last Tuesday, the degree of M.D. was conferred on sixty graduates.

At the recent commencement of the College of Physicians and Surgeons of New York, it was announced that the Cartwright Prize had been awarded to an essay written conjointly by Dr. Hobart A. Hare and Dr. Edward Martin, of Philadelphia. The successful competitors have voluntarily surrendered the prize because their essay had just been awarded a prize elsewhere. It appears that the essay had been put in competition for both prizes, with the expectation that the decision of one prize would be made early enough to permit them to withdraw from the second competition in case they were successful in the first. But owing to delay in the decision of the prize which should have been announced first, and to the absence of the authors from home when the announcement was finally made, there was no opportunity for the intended withdrawal before the award of the Cartwright prize was published.

The award of the Cartwright prize has consequently been reconsidered, and the prize has been awarded to Dr. Ira Van Gieson, Assistant Instructor in Normal Histology in the College of Physicians and Surgeons of New York, for his essay entitled, "Studies in Neural Pathology, embracing, (1) A Report of a Case of Syringo-myelia; and (2) A Contribution to the Pathology of the Laryngeal and other Crises in Tabes Dorsalis."

Dr. Elwood Wilson, a prominent and highly esteemed practitioner of Philadelphia, died at his suburban residence in Delaware County last Sunday, aged sixty-seven years. Dr. Wilson graduated in medicine at the Jefferson Medical College in 1845. Early in his professional career he devoted himself to obstetrics, and he attained a large practice and high reputation in this department. He was formerly lecturer on obstetrics and diseases of women at the Philadelphia Lying-in Charity, and later one of the consulting physicians and president of the institution. He was a member of the American Gynecological Society, of the College of Physicians of Philadelphia, of the Philadelphia Obstetrical Society, and a Trustee of the Jefferson Medical College.

REVIEWS.

Cyclopædia of the Diseases of Children, Medical and Surgical. Edited by John M. Keating, M.D. Vol I. 8vo., pp. 992. Philadelphia: J. B. Lippincott Company, 1889.

We seem to be living in the days of encyclopædias; two on general practice, one each on obstetrics and gynecology, and, finally, the one under consideration. The large *Handbook on Diseases of Children*, edited by Gerhardt, first began to make its appearance twelve years ago, and at that time its chances of success were considered rather problematic. No one, in those days, dreamed of the possibility that in a comparatively short space of time a demand would come for an encyclopædia on the subject of diseases of children written by English-speaking authors. Yet such has been the case, and we see before us the first volume of nearly one thousand pages, to be followed by three more equal to the first in size.

It will be a matter of no little surprise to those who have not followed the development of the literature of pediatrics, when they see how much can be written upon diseases of children. Those, on the other hand, who are acquainted with the enormous strides that have been made within the last fifteen years, will, perhaps, be astonished that a few of the articles in this volume have not received more thorough treatment. However this may be, if we compare the present volume with that of Dewees (1833), or Eberle (1834), American books published in this country, or even with the classical book of West (first published in 1848), it soon becomes apparent how much pediatrics has developed among English-speaking people. We are not too bold when we assert that the most incomplete article of this volume is encyclopædic in comparison with the article upon the same subject in any one of the above-named books.

The effect that the publication of such a work as this encyclopædia must have upon the further development of pediatrics is incalculable. When once the attention of the medical public is called to a subject, its interest is quickly enlisted, and contributions soon flow in to help increase the general fund of knowledge. It has seemed to the writer that our physicians have been drifting in directions neither as useful nor important as pediatrics. Ovariotomists, abdominal surgeons, rhinologists, laryngologists, etc., are to be found in almost every small city east of the Mississippi River. Notwithstanding the assertion made by Jacobi in the splendidly written introduction to the

work, we believe the tendency now-a-days is toward specialism, and when the profession awakens to the fact that the subject of pediatrics is a specialty, broad, liberal, comprehensive, and one which cannot be acquired except as the result of evolution from general practice, it will not then be slow in availing itself of the opportunities afforded by such a work as the one under consideration. Again, not any one of the smaller works on diseases of children is satisfactory or adequate to the wants of the thinking physician. One difficult case elucidated by an author makes a whole volume valuable; the absence of discussion, of exceptions, or modifications, makes it valueless. In the present state of science, small books upon a great, broad, and comprehensive subject must be relegated to the class of text-books, the importance of which must not be underestimated. Every practitioner ought to develop beyond the state of relying upon text-books; for such, this book is invaluable.

It seems necessary to state that some weak articles will be found in a work written by so many authors. No book of cyclopædic character has ever been published in which the foregoing is not fully illustrated. If the volumes which are to follow will be as good as the one just published—and the names of the authors who will write for the forthcoming volumes seem to be ample guarantee for this—this *Cyclopædia of Diseases of Children* will be able to hold its own against any that has appeared.

The editor and publishers have every reason to congratulate themselves upon their success, and the profession ought to be grateful to them for a marked advance in science, as well as decided contributions to our knowledge.

SOCIETY PROCEEDINGS.

AMERICAN MEDICAL ASSOCIATION.

Fortieth Annual Meeting, held at Newport, R. I., June 25, 26, 27, and 28, 1889.

(Specially reported for THE MEDICAL NEWS.)

SECTION OF PRACTICE OF MEDICINE.

DR. FRANCIS DELAFIELD, of New York, read a paper on

CHRONIC ENDOCARDITIS,

in which he discussed why in some cases there are disturbances of the circulation, and why in other cases there are not. These disturbances are due to the endocarditis, the dilatation and hypertrophy of the ventricles, the inflammation or degeneration of the wall of the heart, inflammation of the coronary arteries, abnormal heart action, the associated pulmonary emphysema, chronic endocarditis, and chronic Bright's disease. These act singly or together.

The most important of these are the endocarditis, the abnormal heart action, and the secondary and complicating changes in the kidneys. These conditions he discussed at length, dwelling mainly upon the etiology and symptomatology of the affections.

DR. PEPPER was particularly glad to note the importance attached to the arterial changes in their bearing upon heart lesions. Doubtless when we have more exact knowledge of the changes which occur in the various ganglia of the heart, we shall find that they too play an important *rôle*. Just as recent observers have described changes in the ganglia of the kidneys associated with changes in the vessels and stroma of those organs, so it will undoubtedly be found that there are important changes in the cardiac ganglia which are associated with lesions of the valves or walls, and which exert an important influence on the production of symptoms. In regard to Dr. Delafield's distinction between a chronic inflammation and a deformity, it must be remembered that when only the latter remains, it is of an organ with the closest relations with life, and with the most important and ceaseless mechanical function to perform. The causes of endocarditis are numerous, and often obscure. It may be some antecedent infectious disease has left germs which are exciting morbid action there, and it is becoming clear that some trifling endocardial lesions may be roused into dangerous activity by the invasion of various germs. The relations of the endocarditis with nutritive disturbances, and the danger of recurring congestions and irritations, emphasize the importance of rigid regimen and treatment as long as evidences of active endocardial process are present.

When, however, we have only the results, in the shape of valvular disease, we have thoughts of fundamental importance quite aside from the question of medication. One of the most important concerns the mass of blood and its relations with the needs of the body and with the capacity of the cardiac apertures, and the capacity of the cardiac walls and cavities. The difficulty of the mechanical work which is performed by the crippled organ is determined by the friction to be overcome and the mass to be moved. The state of the arteries has a vital bearing upon this, as well as the mass of blood. Serious symptoms often persist until the latter is reduced by restricted diet, saline laxatives, or continuous venesection. He cited a case in which alarming symptoms of cardiac failure were relieved by epistaxis. If the body-weight be excessive, especially when owing to excessive adipose formation, great and unnecessary strain is thrown upon the heart. Hence it is often necessary to reduce the weight while improving the tone of the system. This is done by gradual exercise, passive or active, and, if necessary, by suitable remedies. Most important and essential is the improvement in the system's tone. Nothing is more injurious than the relaxed and oversensitive state of the system so commonly met with and often associated with the rheumatic diathesis.

DR. OSLER remarked that in the majority of cases of chronic endocarditis no symptoms are manifested. It is not the disease, but the gradual failure in compensation that causes the symptoms.

DR. JAMES TYSON, of Philadelphia, read a paper entitled

THE INDUCTION OF PREMATURE LABOR IN BRIGHT'S DISEASE OF PREGNANCY.

The procedure was recommended: 1. In cases in which in a previous pregnancy there has been puerperal nephritis with grave complications. 2. With a view of saving the life of the patient in all puerparæ in whom there is Bright's disease previous to pregnancy. He had had so many cases of this kind in which death followed upon the first confinement, that he had grown to regard the girl thus affected as walking to her death as she walks

to the altar, and, if the opportunity present, he discourages marriage in the strongest terms. Should it happen, however, that a girl thus afflicted does marry, she should never be allowed to go to term, but premature labor should be induced as soon as the fœtus is viable. 3. Those cases of puerperal nephritis not included in the first and second categories, viz., those in which we have not the knowledge gained by experience with a previous occurrence of the disease in the same patient, and those which are not primiparæ having Bright's disease previous to marriage. They include acquired puerperal nephritis in multiparæ where a previous labor has been accomplished without serious results. In this category no definite course can be laid down. In general, it may be said, that the supervention of uræmic symptoms demands immediate interference, but in consequence of the variety in these, and their occasional simulation by symptoms due to other causes, care must be observed lest an error in diagnosis be made.

As a rule, too, the same symptoms are more serious in robust, plethoric women than in the delicate and less hardy. Bright's disease acquired in the first pregnancy is a very much more serious complication than in a later one, and labor is rarely terminated without grave symptoms.

DR. VICTOR VAUGHAN, of Ann Arbor, stated that certain women always have uræmic symptoms. We do not really know what they are due to. He agreed with Dr. Tyson that premature labor should be induced early in these cases, because, if manifested once or twice, the affection will return, and sometimes very quickly. He cited the case of a woman who had been pregnant several times, and who suffered with convulsions during each pregnancy. During the last pregnancy, twenty-four hours after an examination had shown normal urine, albumin was found, and she passed into uræmic coma. According to his experience, it was wisest not to allow these patients to go to full term, except in primiparæ, in whom it was not justifiable to be too hasty. We know that the poisonous elements are formed from the proteids in the food and tissues. He thought that we could do much with diet in which the proteid food had been discarded, and with free elimination.

DR. I. E. ATKINSON, of Baltimore, thought that the question to discuss was, "Under what conditions are we justified in inducing premature labor?" It is just in primiparæ that we get the terrible results from puerperal convulsions. According to his experience the contracted kidney is the most prolific source of these troubles. Still many patients pass through this dangerous period with happy results. He, however, did not believe in one moment's delay after the mildest symptoms have become manifested. Those suffering with other forms than contracted kidney get along better, as a rule.

THURSDAY, JUNE 27TH.

DR. VICTOR C. VAUGHAN, of Ann Arbor, read a paper on

THE ETIOLOGY OF TYPHOID FEVER.

He stated that the Eberth bacillus is now generally regarded as the true cause of typhoid fever. He showed to what extent the four rules of Koch had been complied with in the study of this germ. After citing the observations of a number of authorities, he stated that the number of cases of genuine typhoid fever in which this germ has not been found when the examinations have been made by competent men is so small that we are justified in claiming that the first of Koch's rules has been complied with. That the second of Koch's rules has been complied with there is no doubt. Pure cultures of this germ are to be found in every bacteriological laboratory. It grows rapidly in our artificial media and its characteristics of growth are well known. He called attention to the most important of the numerous and interesting attempts which have been made to induce the disease in the lower animals by inoculation with the Eberth germ. Thereby it was shown that all attempts to accomplish this have so far been without success. Experiments show not only that the germ fails to multiply in the lower animals, but that, when introduced by inoculation, it soon dies.

The bacteriologist says here: "The lower animals do not have typhoid fever, and we must not conclude from the failure to induce this disease in lower animals with the Eberth germ that the bacillus is not the true cause of typhoid fever." If we could experiment upon man he would have no doubt that we would be successful. Hence, he wished to discuss this germ from the standpoint of a chemist.

He thought that it was now time for us to add to the rules of Koch the following: "Before any microörganism can be considered the true and sufficient cause of a given disease, it must be shown that the chemical products of that germ are capable of producing the characteristic symptoms and lesions of that disease in an acute form." This demonstration has been given in anthrax and tetanus. Recent extended researches by Brieger on this point failed to discover in cultures of the Eberth germ any real typhoid poison. With this in view we certainly cannot say that the Eberth germ has been demonstrated to be the true and sufficient cause of typhoid fever. He was forced, from the evidence at hand at present, to concur with Brieger, who is inclined to the opinion that Eberth's germ plays a secondary *rôle* in the causation of this disease.

Since, then, there seems to be very good reason for regarding typhoid fever as due to mixed infection it may not be without interest to inquire briefly into some of the experiments made with impure culture or with germs other than the Eberth. He detailed experiments by Murchison, Klein, and Bohardt, by feeding with typhoid stools, and those made by Motschutkoffski and Walder, by inoculation with blood of typhoid patients, which were unsuccessful. Birch-Hirschfeld's experiments were referred to, as also those of Brautlecht, who employed organisms obtained from drinking-water which had been used by those who subsequently had typhoid fever.

Drs. Vaughan and Novy obtained from drinking-water from Iron Mountain, where there had been a severe epidemic of typhoid fever, a germ which they could not distinguish, by microscopical appearance, reactions with staining reagents and growth in gelatine tubes and on potatoes, from the Eberth bacillus.

March 5, 1888, they inoculated three dogs with this germ taken from a beef-broth culture, twenty days old. The germs were washed with sterilized water, then suspended in the same menstruum and injected into the peritoneal cavity, all precautions, such as shearing off the hair, washing first with a solution of bichloride of mercury and then with alcohol, having been taken, and

neither at the point of inoculation nor anywhere else in the animals was there at any time any evidence of septicæmia. The dogs were placed in a large cage with a fourth one which was employed as a control. For some four or five days after the inoculations, they took the temperature of the animals daily, but there being no variation beyond the normal limits they supposed the experiment to be negative, and neither of them visited the animal room until the second day of April, twenty-eight days after the inoculation, when the janitor told them that one of the dogs had died and the two others had grown very thin and seemed to be sick. A post-mortem examination surprised them by revealing very prominently some of the lesions of typhoid fever. The animal was very much emaciated. Drs. Hendricks and Brewer were asked to make the post-mortem and the following is their report on the same:

"The weight of the body was twenty pounds. Upon the abdominal cavity being opened the mesenteric fat was observed to be pink with hemorrhagic spots. The bloodvessels of the intestines were found to be highly injected with numerous points of hemorrhagic infiltration. On the mesentery near the cæcum were large hemorrhagic spots. The lower inch and one-half of the ileum was distended and covered externally with clotted blood. The mesenteric glands were enlarged to four or five times their normal size and each contained hemorrhagic spots. The glands of the vermiform appendix were much enlarged and were pitted in the centre. Under the mesentery of the cæcum was a plastic exudate, almost transparent. The descending portion of the duodenum showed numerous bright hemorrhagic spots along the line of its junction with the mesentery.

"Along the upper portion of the ileum the intestine presented a greenish macerated appearance and a soft pultaceous feel. Air blown into the intestine escaped through the walls at this point. The mucous membrane of the ileum was swollen and Peyer's patches enlarged, but there were no distinct ulcerations. The liver was indurated and of a deep cherry color, weight twenty-three ounces. The kidneys were enlarged to twice the normal size and were dark in color. The spleen was enlarged and of a dark purple color. The stomach was contracted and its mucous membrane showed a few hemorrhagic spots. The lungs were normal and the heart in diastole and free from clots. The thymus and lymphatic glands were enlarged."

He regretted exceedingly that no attempt was made to obtain cultures from the mesenteric glands or spleen of this animal. The next day they took the temperature of the other dogs with the following results:

	No. 2.	No. 3.	Control.
April 3, 3.00 P. M.	105.0°	103.8°	100.8°
" 3, 5.30 P. M.	105.6	104.4	100.4
" 4, 9.00 A. M.	102.8	104.6	100.8
" 4, 3.30 P. M.	103.0	105.0	101.2
" 5, 10.00 A. M.	105.0	103.8	101.4
" 5, 2.30 P. M.	104.0	103.8	101.7
" 6, 9.30 A. M.	105.6	104.8	101.4
" 6, 3.00 P. M.	106.0	106.2	101.8
" 7, 2.30 P. M.	106.8	105.0	101.0
" 7, 7.30 P. M.	106.8	105.2	101.0
" 8, 11.30 A. M.		104.0	101.4
" 8, 6.00 P. M.		104.2	101.0
" 9, 10.00 A. M.		101.0	101.0
" 9, 6.00 P. M.		101.0	101.5

During the night of April 7th No. 2 died. The post-mortem revealed practically the same condition as found in No. 1, save that there was no perforation of the intestines. As is seen from above figures, No. 3 had no fever on April 9th, and remained in apparent health as long as he was under observation, which was until June 18th.

Twelve other dogs were inoculated April 18th with a subsequent culture of this organism. In four out of twelve the temperature at the end of the first week registered between 104° and 105°, by the close of the second week it had fallen to 103°, and during the next week became normal and remained so. In each of three others the highest temperature was 103.5°. The others were not apparently affected. Not only did the germ seem to lose its virulence, but it soon failed to grow in the culture tubes and died out altogether.

Notwithstanding the marked resemblance of these cultures to those of the Eberth germ, Dr. Vaughan concluded from the effects obtained that they were either a wholly different organism or an impure culture. He did not know that these experiments can be considered of any special importance, but taken together with those of Brautlecht, he thought that they give encouragement for further experiments with microörganisms which may be obtained from the drinking-water used by those who have typhoid fever.

During the past six months he had spent four or five hours a day upon the study of the etiology of typhoid fever, approaching the work from a wholly different standpoint from that indicated in the preceding pages. He began last December a chemical study of typhoid stools, with especial reference to the presence of ptomaines in the same. He soon met with great difficulty. In the first place, it was not always easy to have at hand material in sufficient quantity, and although friends practising where epidemics of the disease existed, kindly took the trouble to endeavor to supply him, this difficulty alone was sufficient to cause him to alter his plans. Moreover, the coloring matter present was taken up by his solvents, and it proved no light task to exclude them. He finally adopted the following method: The stools were received directly from the patient in a sterilized vessel. With a sterilized platinum needle flasks of meat-broth, previously sterilized, were inoculated with these stools. These flasks were then kept at a constant temperature of from 38° to 40° C., for varying periods of time, after which he attempted to isolate any ptomaines that might be present. Thus it will be seen that he worked with a mixed culture containing all germs present in the feces, the object being to ascertain whether or not the basic substance or substances formed in such cultures would differ from the ptomaines of Eberth's bacillus.

The method of isolating the ptomaine was as follows: After the cultures on meat broth had been kept in the incubator at the temperature of from 38° to 40° C. for from ten to twenty days, they were filtered and rendered feebly acid with hydrochloric acid. At this time the cultures were invariably ammoniacal. The acidified filtrate was then evaporated to dryness, or as nearly to dryness as could be done, on the water-bath. The residue was extracted with absolute alcohol, the extract precipitated with an alcoholic solution of mercuric chloride, saturated at the temperature of the water-bath, the precipitate was collected, washed with alcohol, sus-

pended in distilled water, and decomposed with hydrogen sulphide. The mercuric sulphide was removed by filtration, the filtrate evaporated to dryness on the water-bath, and this residue extracted with absolute alcohol, the extract precipitated with a solution of platinum chloride in absolute alcohol, the precipitate collected, washed with absolute alcohol and dissolved in distilled water. The aqueous solution was concentrated on the water-bath until the platinum compounds began to crystallize out. This aqueous solution contained two or more platinum compounds; but so far he had given his attention to only one of them. This forms in rhombic prisms which are purified by repeated recrystallization. For purposes of physiological experimentation, this platinum salt was decomposed with hydrogen sulphide, and the filtrate concentrated nearly to dryness on the water-bath, when the crystals form. This is the hydrochloride of the ptomaine.

The following experiments show the action of this ptomaine:

February 6, 1889. An aqueous solution, neutral in reaction, of this ptomaine was injected under the skin over the abdomen at 2.50 P. M. The temperature in the rectum before the injection was 100.5°. At 3.35 the temperature was 102.6°; at 4.10, 103.2°. About this time severe purging set in, and continued with intermissions and prolonged straining for an hour. At 4.35 the temperature was 103.4°; at 5, 103.9°; at 5.30, 104°; at 6, 103.9°. The temperature was not taken again until 9 A. M. Feb. 7, when it was found to be 102°; at 12, 101°; at 6 P. M., 100.5°. Between 2.50 P. M. and 5.30 P. M., or within two hours and forty minutes, the temperature of this animal went up 3.5°. The straining and purging were also marked.

May 18, 1889, he gave by the mouth an aqueous solution of the crystals to a dog, which weighed fifteen pounds. The rectal temperature before the administration of the poison was 101°; the time of administration, 3 P. M. At 3.15 retching and vomiting set in, and continued at intervals for more than two hours. At 3.30 the temperature was 103°, an elevation of 2° within a half hour. At 3.55 the animal began to purge, the first discharges contained much fecal matter, but the subsequent ones were watery, and some of them contained mucus plainly stained with blood. At 4 the temperature was 103.5°, and remained the same at 4.30. The animal was not seen again until 10 A. M. the next day, when its temperature was 100.5° and recovery seemed complete.

He referred to other experiments with this ptomaine, but as they were repetitions of the above in general, he did not detail them. He did not place any great stress upon the elevation of temperature when that was the only symptom, but when taken with the gastro-intestinal disturbances he thought he had reasons for hoping that the discovery of this ptomaine may prove of value in elucidating the etiology of typhoid fever. Of course, further experimentation is necessary. It remains to be seen whether or not typhoid stools invariably contain germs capable of producing this chemical product, also whether or not the same germs are contained in normal stools, or in those of any other disease than typhoid fever. Moreover, he hopes by means of making plate cultures to determine whether this ptomaine is the result of the activity of a single germ or of two or more microorganisms. The stools used in these experiments were from undoubted cases of typhoid fever and from three widely separated outbreaks of the disease.

Some of the conditions influencing the formation of this poison may be of interest. It was found most abundantly when the cultures were kept at a temperature of 40° C. for a period of ten days. After this time the amount of the yield grows less, though he has found traces after twenty days. He obtained larger quantities from cultures made on pork broth than upon beef broth, though the poison was never absent in the latter. From six quarts of pork broth he obtained as the greatest yield nearly two grammes of the platinum compound. Though he had made several partial ultimate analyses of the platino-chloride he was not quite ready to give a formula for this base, nor did he care to propose a name for it at present.

The platino-chloride crystallizes in fine rhombic prisms and the hydrochloride in red needles, which he showed. The red color seems to be inherent to the substance and not due to impurities. The hydrochloride obtained from the decomposition of the mercury compound has the same color as that from the platinum compound. The mercury and platinum compounds are insoluble in absolute alcohol, soluble in water. The hydrochloride is soluble in both water and alcohol.

DR. W. H. WELCH, of Baltimore, said that he must protest against accepting one condition which Dr. Vaughan formulated, viz.: "That before we admit that a certain microörganism is the cause of a disease, we must isolate from cultures of this organism chemical products which are capable by inoculation or feeding of producing the symptoms of the disease." It is certainly an important addition to our knowledge of a disease to become acquainted with such chemical products, but this is not essential to a belief in the causative agency of a specific organism. If Dr. Vaughan's condition be accepted as an essential link in the chain in proof, then we have no sufficient evidence that many recognized infectious organisms, such as the spirillum of relapsing fever, the bacillus of leprosy or even the tubercle bacillus are the causes of their respective diseases. From our present knowledge we are justified in believing that a microörganism which is invariably associated with a disease, which is found in the lesions of a disease and in situations which explain the symptoms and lesions, and which is never found except in association with the disease, must be regarded as the cause of the disease. Where, in addition to this, we are able by experiments on animals to reproduce the disease by inoculation of pure culture, this additional proof is most welcome. But in many infectious diseases we cannot furnish this last method of proof, either because we have not been able to isolate and cultivate the suspected organism, as is the case with relapsing fever, or because animals available for experiment are not susceptible to the disease, as seems to be true of typhoid fever and cholera. For this reason Koch has stated that it is not absolutely necessary that we reproduce the disease experimentally in animals by inoculation before we admit that a given organism found associated with a disease under the conditions stated is the specific cause of the disease. The evidence Dr. Welch believed to be conclusive, that the typhoid bacillus is the specific cause of typhoid fever. Dr. Vaughan's emphasis of the necessity of demonstrating the chemical products of pathogenic microörganisms

before we accept their etiological significance is based upon the assumption that infectious organisms produce their disastrous effects solely by their chemical products. But this assumption is quite unwarrantable; in fact, there is reason to believe that while some pathogenic organisms act by chemical products, others do not so act.

As Dr. Vaughan himself is doubtful as to the interpretation of his experiments on dogs, Dr. Welch was not inclined to attribute to them any bearing upon the etiology of typhoid fever, without further information than we now possess. Dr. Vaughan is to be congratulated upon the isolation from the typhoid stools of a definite crystalline substance with such interesting properties, but as Dr. Vaughan himself has stated, it will be necessary to make control chemical observations with diarrhœal and other stools not derived from typhoid patients, before the relation of this substance to typhoid fever becomes clear.

DR. VAUGHAN said that he would give his attention wholly to the criticism of Prof. Welch, who had said that the first of Koch's rules is all that is necessary in order to prove that a given germ is the cause of a disease: in other words, because Eberth's germ is found in every case of typhoid fever it must be the cause of that disease. He did not think that all the failures to induce the disease by inoculation with this germ are of any significance as to its cause. When Koch first promulgated his four rules, and pronounced that they must be complied with before the causal relation of a germ to a disease should be considered as demonstrated, the scientific accuracy of such a demonstration won the confidence of the medical world. Now, Prof. Welch says that three of these four rules are unnecessary. He claims that the presence of the Eberth germ in the altered tissue of typhoid fever is a proof that these germs cause typhoid fever. How does he know that the presence of the germ is the cause and not the result of the disease? He reaches this conclusion by reasoning from analogy. This kind of reasoning may have its value, but it is not scientific. Suppose that an inhabitant of some far-off planet should, by means of optical instruments, be able to discern the inhabitants of a certain portion of the globe. Suppose that the portion of the globe which should fall under his observation to be the frigid zone. Here he would find the inhabitants living in houses built of snow and ice, and, reasoning by analogy, he might conclude that all the inhabitants of the earth live in houses of this kind. The reasoning of Prof. Welch is just as unscientific as that in the supposed case of the planetary observer. Condensed, his reasoning would be about as follows: (1) The bacillus of consumption is found in every case of consumption, and the Eberth germ is found in every case of typhoid fever. (2) The bacillus of tuberculosis has been demonstrated to be the cause of consumption. (3) Therefore, the Eberth germ is the cause of typhoid fever.

DR. J. C. WILSON, of Philadelphia, presented a paper on

THE PROPHYLAXIS OF TUBERCULOSIS.

In it the following questions were submitted to tests for settlement: 1st. Is pulmonary consumption hereditary? 2d. Is it contagious? 3d. Is it preventable?

After thoroughly sifting all evidences offered for the first question, he affirmed that pulmonary consumption, subjected to the tests by which we determine the question in regard to the infectious diseases in general, does not appear to be hereditary in the ordinary sense, and that the congenital predisposition to the tuberculous disease is much less general than to several other infectious diseases, notably the eruptive diseases of childhood.

As to the second question, he summed up his researches with the statement that tuberculous diseases respond in every important particular to the tests by which we determine the contagiousnes of the other infectious diseases. Tuberculosis is transmitted by inoculation, by direct contact, by means of food and drink ingested; finally, by means of the respired air.

In the discussion of the third question he remarked that the chief avenues of contagion are the digestive and respiratory tracts. Tuberculosis is acquired by infected foods and by the inhalation of air containing tubercle bacilli and spores. The rigid inspection of all cows in dairies and of all animals slaughtered for food and the destruction of those found to be infected would constitute the chief measure of prophylaxis as regards infection by food. A second measure would be the systematic care of the milk until consumed.

Reduced to its simplest form, the problem of prophylaxis against the spread of the tuberculous diseases among human beings consists in the proper care of the fresh expectoration of consumptives. Not dangerous while moist, it becomes, when dried, the chief means of the spread of the disease, from the lesions of which alone it is derived. It should be collected in suitable vessels and kept in a moist condition until it has been destroyed by fire or discharged into sewers under such conditions as will insure its conveyance to places where it is not likely to become a source of danger. Spitting upon the floor, or in the streets, or into handkerchiefs or towels, should in all instances be avoided. Suitable cuspidors should be used at home and pocket spit-cups carried when without. An individual who is well on the road to recovery, may, by self-inoculation, if he do not with the greatest care destroy his sputum, diminish greatly his chances of recovery. The early recognition and treatment of pulmonary consumption constitute in themselves an important measure of prophylaxis.

DR. STOCKTON took issue with the author on one point —*i. e.*, diathesis. He quoted a case occurring in an orphan asylum, in which a single child was attacked with acute tuberculosis, while no other child was ill. Why was this so? It can be explained on no other ground except lack of resistance. It seems so evident that something beside contagion is concerned in the etiology of tuberculosis that the causes may be divided into two classes: 1st, contagion, and, 2d, non-resisting soil.

DR. SOLLY, of Colorado Springs, thought that he had observed in Colorado strong evidences of the contagious character of the disease. It was found occurring in all individuals, and attacking any one with the slightest exciting cause.

DR. HERRICK was not ready to accept absolutely the contagious character of tuberculosis. It might be a matter of mental deficiency on his part, still a large number of facts were to him not explicable.

DR. SOLIS-COHEN, of Philadelphia, said that the last speaker need not fear being accused of mental deficiency so long as one of the great medical minds of the century, Dr. B. W. Richardson, of London, occupied the same

position of wholesome scepticism. It would be a mistake to assume that the infective action of microbic parasites is the sole cause of consumption. There are other parasites—the entozoa, which descending from non-parasitic organisms have, through the circumstances attending their evolution, taken upon themselves the parasitic cycle. As Dr. Vaughan's investigation proceeds in the one direction to determine in what way bacteria are toxic, so we may look in the other direction to see which preceded chronologically, the microörganism or the disease, alike in the life of the individual and in that of the race. May we not conceive that their evolutionary history is like that of the entozoa; that, originally innocuous, they found in the degenerated tissues of disease a favorable environment, and thus took up their parasitic cycle, gaining, perhaps, a certain power of carrying infection. He did not deny their infectious power, but he did submit that the evidence of their sole power of originating disease is not conclusive. The evidence as to consumption seems to indicate an hereditary diathesis, an hereditary failure of nutrition, and that upon this bacillary tuberculosis becomes engrafted as an epiphenomenon.

DR. WILSON, in answer to Dr. Stockton's remarks, stated that there are cases of tuberculosis as incapable of explanation as some of the single cases of typhoid fever occurring in a locality. The tubercular nature of the disease is demonstrated. Those who do not accept the doctrine have nothing to offer in its place.

DR. SOLOMON SOLIS-COHEN then read a paper on

FOOD IN THE TREATMENT OF PULMONARY CONSUMPTION.

Though the paper is therapeutic, yet, as therapeusis must be founded on sound pathology, it is necessary to state that the morbid physiology of the disease, and not its bacteriology, is considered the fundamental indication. In deference to prevailing views, tuberculosis may for the present be granted to be the history of the growth, life, and activity of a bacillus. But for rational treatment we must revert to the views of Niemeyer, who said that the danger of phthisis is tuberculosis; or to those of Rush, who declared that tubercle and other anatomical lesions were "the effect, not the cause of pulmonary consumption;" and recognize the disease we have to combat not in epiphenomena of possible microbic origin, but in the consumption, the aberration of nutrition, which precedes the entrance of the microbe. Consumption is a disease of nutrition, whose exact mechanism is as yet unknown, though the results of prolonged observation justify us in considering heredity, unhygienic surroundings, and, in general, those influences called "depressing," as among its remote or proximate causes; the pulmonary form being further dependent upon errors in respiration, whether of the substances respired or of the performance of the act.

Thus we dismiss as futile, microbicidal treatment; and recognize ptomaines of bacillary origin only as giving rise to intercurrent symptoms which may call for antidotal or symptomatic treatment. Fixing attention upon the malnutrition, which is not a mere "predisposition" to succumb to a bacillus, but the essence of the whole morbid process, we combat it by direct measures, hygienic and medicinal; the latter secondary, the former all-important. Chief among hygienic measures is food. Food consists not alone of meat and drink, but also of air. Full respiratory diet is necessary to the utilization of alimentary diet. As in diabetes, so in phthisis, there is imperfect metabolism of carbohydrates. Experience shows a nitrogenous dietary to be best. Debove has shown that consumptives can assimilate a quantity of food far in excess of the needs of the healthy organism. This excessive quantity should be supplied; though resort to the stomach-tube, as in Debove's experiments, can be reserved for special cases.

Meat, principally beef, with milk, fish, eggs, leguminous vegetables and greens, should form the bulk of the dietary; with the addition of fat, in large quantities, in the form of cream, butter, oil dressing for salads, or, if necessary, cod-liver oil or oleaginous inunctions. Alcohol is a food in consumption. It should be taken with malt, milk, cream, glycerine, or cod-liver oil. Not more than three, at most four, hours except during sleep, should be allowed to elapse without taking food. Milk-punch on going to bed, and a glass of wine or spirits with liquid peptonoids in case of waking during the night, were strongly urged. Hot water before meals, lavage if necessary, to prepare the alimentary tract for the digestion and absorption of increased food, and the free drinking of water to wash out waste products, are essential to success. Predigested foods may be employed with great benefit, especially peptonized milk and beef peptonoids. In case gavage is resorted to, they should be used almost exclusively. Gavage is best preceded by lavage with an alkaline solution and chloroform water.

Proper alimentary diet being secured through overfeeding, and the digestive tract and its adnexa being kept in good condition, proper respiratory diet must be supplied. Open-air life, exercise on horseback, or bicycle, voluntary respiratory gymnastics, may suffice when the patient is still strong enough. In the majority of cases there must be some artificial aid. The inhalation of compressed air, with or without expiration into rarefied air is the best means. Apparatus should be simple and cheap, so that the patient can use it at home. The principles laid down by Waldenburg are the correct ones. Cohen's apparatus consists of a bellows and a small gasometer modelled upon Waldenburg's. Its advantages are cheapness, simplicity, and small size, fitting it for home use. After patients are sufficiently advanced toward recovery, the pneumatic resistance valves of the author, a still more convenient and very cheap pocket apparatus (costing about five dollars) may be used. It may be used in the first instance with strong patients. It is also useful as a prophylactic measure with ill-developed children. It gives the effects of breathing against pressure—*i. e.*, into compressed air, or out of rarefied air.

The effects of pneumatic measures are to increase the volume of respiratory air, open up unused air-cells, facilitate expulsion of pathological products, increase gaseous exchange, facilitate absorption of oxygen by the hæmoglobin, while, at the same time, the volume of blood and the activity of circulation in the lungs are increased, bringing more corpuscles into contact with the increased volume of oxygen. Penetration of blood into the tissues, tissue respiration, and production of lymph, are also increased. Thus local and general nutrition are powerfully stimulated, and an improved respiratory habit, and increased respiratory and circulatory power are gained. The products of digestion are properly oxidized and

utilized, immature tissue is destroyed and expelled. The promotion of sleep is one of the most marked effects.

The physician puts them, by altering his patients' environment in the manner described, into a condition where natural powers complete the cure, and bacilli need not be feared. Illustrative cases were cited, and the conclusion reached that the proper treatment of consumption is not microbicide, but nutrition.

AMERICAN NEUROLOGICAL ASSOCIATION.

Fifteenth Annual Meeting, held at Long Branch, N. J., June 26 and 27, 1889.

(Continued from page 27.)

JUNE 27TH.—MORNING SESSION.

DR. GEORGE W. JACOBY, of New York, read a paper entitled

A CONTRIBUTION TO THE STUDY OF ANÆSTHETIC LEPROSY, WITH SPECIAL REFERENCE TO PARTIAL SENSORY DISORDERS.

The points to which particular attention should be paid in all cases were, the electrical excitability of the muscles, the condition of the reflexes, the presence or absence of fibrillary twitchings, and the condition of sensation. Upon these data depended the diagnosis between anæsthetic leprosy and syringomyelia, as well as that of the central or peripheral localization of the leprous process. The conclusions arrived at by the author from the analysis of his own and other cases were, that the differential diagnosis between the two diseases could not always be made; that partial sensory disorders are not characteristic of syringomyelia, but may occur in anæsthetic leprosy as well as in purely peripheral affections; and, finally, that a differential diagnostic point between central and peripheral loss of temperature sense may lie in its complete loss in one case, and its partial in the other.

DR. STARR said that the same question as to the differential diagnosis between syringomyelia and anæsthetic leprosy had only recently occurred to him. Three weeks ago he had seen a case with Dr. Prince A. Morrow, of New York, in which there had been a gradual onset of an atrophic and anæsthetic affection of the right arm. He came from the Sandwich Islands, and had been exposed to leprosy. There was anæsthesia to temperature and pain, but not wholly to touch, along the hand and part of arm. There were three small reddish-brown spots on the arm, which Dr. Morrow considered leprous in character. The idea of syringomyelia at once occurred to him, but the history of exposure in a leprous country sufficed to make anæsthetic leprosy at least the more probable nature of the disease; but without such history it would have been almost impossible to make the diagnosis. As to the matter of partial loss of sensation, in the cases of multiple neuritis and *beri beri* he had seen, the sensory loss was complete, with the exception, however, of muscular sense.

THE PRESIDENT remarked that he had now under observation a case of leprosy, but had as yet made no careful examination of the temperature sense. His case illustrated the ease of diagnosis at an early period, when confusion with syringomyelia could not occur. The patient had a wine-colored eruption on the entire left leg and part of the thigh, the foot being free, and there were three or four similar spots on other parts of the body. There was distinct analgesia and some anæsthesia in these areas, but there was no paralysis or atrophy. The patient had come from the Sandwich Islands. The well-defined limitation of anæsthetic areas showed that it could not be neuritis. Of late, the anterior leg muscles had become paretic, but there was no reaction of degeneration. The left hand was beginning also to manifest similar symptoms. There were no ulcers.

DR. C. K. MILLS had seen two cases of leprosy. He thought the author's point with regard to partial sensory disorder very interesting, but he did not see why there should not be partial disturbance also in neuritis, and, in fact, in traumatic neuritis it was quite frequent. The nature of the sensory disturbance depended upon the extent of the injury to the nerve. In ordinary multiple neuritis it might be true, as Dr. Starr insisted, that there was complete loss of sensation, through destruction of all the sensory fibres. He did not see, however, why the sensation to cold should not be injured as much as any. It should be borne in mind that in all infectious diseases attacking the nervous system, there was a tendency to seize upon the central as well as the peripheral portions at the same time.

DR. GRAY agreed with the last speaker as to partial sensory disorders met with at times in peripheral neuritis. He had observed it also in multiple neuritis where, for instance, there was impairment of touch and temperature sense, yet the pain was excruciating. He did not see that it was easy to diagnosticate syringomyelia, and Wichmann and Starr had given no rules for diagnosis in their pamphlets. He believed that no one had made a diagnosis of syringomyelia in life.

DR. STARR stated that Schulze had made the diagnosis in three cases, which had been substantiated by autopsy. The points for diagnosis were the general conclusions drawn from a study of collected cases. Anna Baumler had brought together one hundred and sixteen cases, to which thirty or more had since been added.

DR. GRAY thought these diagnostic points would apply to many other spinal lesions.

DR. BIRDSALL had had similar ideas to those of Dr. Gray as regarded the diagnostic indications in syringomyelia until he had read Roth's collection of cases. In a certain number of such cases there were clinical pictures differing altogether from other spinal lesions and from peripheral neuritis. Disturbance of the temperature sense was the particular characteristic. Still, the testing of this sense had been constantly neglected in studying other spinal cases, and it was possible that it might often be disturbed in other spinal disorders. It was hard to see how any other lesion could produce precisely the same symptoms as those of syringomyelia. It was a question whether tracts for temperature and pain could be localized in the cord. Peripheral nerve lesions might cause injury to some sense fibres and not to others, although generally all are injured, particularly where the inflammation is truncal in character. There might be partial sensory disturbance in dermal forms.

DR. GRAY said it was easy to localize disease in the anterior cornua, in the lateral and posterior columns of the cord, but the diagnosis of central lesions was very difficult. The fact that out of one hundred and fifty cases of syringomyelia only three had been diagnosticated during life proved the truth of his assertion. The

diagnostic suggestions given were, therefore, empirical. The presence or absence of temperature sense had not been sufficiently tested as yet. How would one distinguish a chronic central myelitis?

DR. BIRDSALL stated that central myelitis began acutely and thus differed from the slow advance of syringomyelia.

DR. MILLS thought the question of partial sensory disorder most interesting. But he thought that there would be more apt to be partial disturbance in a truncal neuritis than in a dermal.

DR. PETERSON asked the President if the tendon reflexes were exaggerated in his case of leprosy, and was answered in the affirmative. He had asked this because he had recently read an interesting study of the reflexes in anæsthetic leprosy made by Dr. Suzuki, of Tōkyō, and published in the *Sei-I-Kwai Medical Journal*, in which there was an analysis of seventeen cases. One had normal reflexes, while all the others had increased tendon jerks, and in some of the cases there was even ankle-clonus. The conclusions arrived at by the author were similar to those of Dr. Jacoby.

The PRESIDENT called attention to the fact that so many cases of leprosy were now being continually imported into the United States. It seemed as if the country were threatened with its domiciliation. It was a question whether it was not the duty of physicians having such cases to report them to the authorities.

DR. SINKLER mentioned the recent presence of two cases in Philadelphia. The physician in charge had been fined by the Board of Health for not reporting them.

DR. PRINCE wondered at the manner in which leprous patients were allowed to go about, and thought also that the attention of the authorities ought to be called to the disease, and reports to the Boards of Health ought to be required.

DR. GRAY knew that in the East where the disease is prevalent, isolation is practised. He wished to know what the actual danger of contagion was.

DR. BRILL said that the attention of the New York Board of Health had already been called to the matter.

DR. JACOBY, in closing the discussion, said that Schulze was altogether too positive in his assertions. This author went so far as to contend that cases of leprosy where cavities had been found in the cord were not leprosy at all but syringomyelia. As for himself, he thought a central lesion probably often exists in this disease, although it is well known that the essential pathology lies in a truncal neuritis. A simple dermal neuritis could not be assumed in leprosy. In his case, for instance, the indurated and swollen ulnar nerve could be distinctly felt. He did not agree with Dr. Gray that the diagnosis of syringomyelia could not be made. The only danger lay in mistaking it for leprosy. He had, only last evening, come across a work of Suzuki mentioned by Dr. Peterson, and had noticed the identity of the conclusions of that author with his own, although they were reached from different points of view.

DR. F. X. DERCUM, of Philadelphia, then presented two contributions entitled, respectively,

A DESCRIPTION OF TWO CHINESE BRAINS

and

A NOTE ON THE PLI DE PASSAGE INFERIEURE INTERNE IN THE HUMAN BRAIN.

He exhibited the brains described. Dr. Mills had made a morphological analysis of one in 1886, and descriptions of three Chinese brains had been added to literature by Moritz Benedikt. The six brains thus far analyzed exhibited unusual complexity due to excessive sinuosity of the gyri, and a tendency to excessive transverse fissuration. The frontal lobes were especially large and complex. There was unusual confluence of fissures indicative of a low degree of development, such as is often seen in the negro's and sometimes in the white man's brain. There was unusual length of the parallel and Sylvian fissures, and eversion of the orbital and temporal lobes.

DR. MILLS said that it was very important to keep adding to our morphological descriptions of such brains, until accurate deductions could be drawn from a very large number.

DR. SPITZKA stated that the dictum that a tendency to confluence of fissures indicated a low type of development was not accepted by most anthropologists. The more brachycephalic the skull, the greater was the development of transverse secondary folds. The elephant, which stands among the highest of mammals, has a broad skull and a tendency to confluence of fissures. The Chinese were not low in development. The internal pli de passage in the negro and idiot was significant only when the general cortical development was poor. The real cause of the location of the chief sulci lay in the inherent architecture of the brain, and was due to the arrangement of groups of cells and fibres, but the secondary and tertiary sulci might be influenced by other factors, such as the course of vessels. While we might never be able to localize the higher functions of the mind, there was something in the physiognomy of the Chinese brain which struck him as differing altogether from that of the Caucasian. But it was not the same difference as was noticeable between the negro and Caucasian brains. The peculiar moral attitude of the Chinese pointed to some relation between the structure of their brains and the character of their minds. Still, he had observed a great difference between these two Chinese brains, and there was no feature in them which might not be reproduced in the Caucasian brain.

DR. DERCUM had not wished to imply that transverse fissuration was indicative of a low type, but thought the unusual confluence showed a lack of cortical development. He did not consider them brains of a low type, but many features such as were found in the brains of the negro and ape were found here also. The excessive sinuosity, however, indicated a higher cortical development. For instance, in one brain there were five well-developed frontal gyri.

DR. SPITZKA had the same idea as Dr. Dercum. As compared with the Caucasian brain, the Chinese was in some respects inferior, and in others exhibited a superabundance of gyri. He spoke of the resemblance between the negro and ape brains. The differences between the brains of the ourang-outang and chimpanzee were greater than those between the brains of the chimpanzee and a human being. There was no uniform appearance of the ape's brain. Voigt and another had classified the human brain into three types: the Negro, Mongolian, and Caucasian, corresponding somewhat to the three lower types of the gorilla, chimpanzee, and ourang-outang.

DR. M. ALLEN STARR, of New York, then read a paper entitled

THE PATHOLOGY OF SENSORY APHASIA, WITH AN ANALYSIS OF FIFTY CASES IN WHICH BROCA'S CENTRE WAS NOT DISEASED.

In all of these cases collected by the author some form of sensory aphasia was present, and in all the lesion lay in the posterior lower third of the brain. In seven of the cases there was pure word-deafness, and in these the lesion was limited to the posterior portion of the first and second temporal convolutions. In eleven cases there was pure word-blindness, and in these the lesions were found distributed either in the angular gyrus, the occipital lobe, the temporal convolutions, or the inferior parietal region.

In seven cases word-deafness and word-blindness were coexistent, although the use of language was not lost; and in these the temporal convolutions were involved, extending in some to the inferior parietal, angular, and occipital convolutions. The practical application of the localization of aphasia lesions is obvious, for the regions concerned in speech are especially accessible to the surgeon.

Another fact of interest is, that it seems to be proven that there is no ideational centre. Any idea may be impaired, but cannot be wholly destroyed, by a single cortical lesion. Thought being regarded as the play of consciousness along association fibres between sensory centres cannot be localized.

DR. LLOYD had now a case of simple homonymous hemianopsia without psychical or word-blindness, and wished to know whether there was any diagnostic importance in this condition as to localization. Was there a preponderance of one hemisphere over another as regarded sensory memories of language?

DR. STARR said that the matter of psychical blindness had recently been discussed by Wernicke and another. A lesion affecting bilaterally both occipital lobes or the association tract produces psychical blindness, but a lesion along either tract itself does not cause this condition. Nine cases of psychical blindness from lesion of one hemisphere alone had been reported.

THE ELECTION OF OFFICERS FOR THE ENSUING YEAR

being then in order, the following were chosen:

President.—Dr. E. C. Spitzka, of New York.

Vice-Presidents.—Dr. Wharton Sinkler, of Philadelphia; Dr. H. M. Lyman, of Chicago.

Secretary and Treasurer.—Dr. G. M. Hammond, of New York.

Councillors.—Dr. Henry Hun, of Albany; Dr. C. L. Dana, of New York.

(*To be concluded.*)

NEWS ITEMS.

An International Courtesy.—Under this heading the *British Medical Journal* of July 6th contains the following editorial:

DR. BILLINGS, the accomplished American physician, whose address at the International Medical Congress in London excited much admiration, and whose works are well known and greatly esteemed by all of us, has recently passed through London—where he has been the guest for a few days of Dr. Ord—on his way to Oxford, to receive there the distinction of an honorary degree in law at the annual encænia. Being charged with the preparation of the forthcoming census of the United States he could make but a brief stay, and is already on his way home, otherwise we might have hoped to have seen him at our London meeting.

Few could have deserved this new honor better. Dr. Billings is still a comparatively young man when the work which he has done, the position which he fills, and the honors which he has obtained are considered. He was born in Indiana in the year 1838. He took his degree of M.A. at Miami University, Ohio, and the degree of M.D. at Cincinnati, Ohio, in the year 1860. In the next year the war of secession broke out, and he entered the Federal military service. His energy and abilities at once marked him as a man to whom serious responsibilities should be entrusted. He was Medical Inspector of the Army of the Potomac in 1863 and 1864. He served with the Federal army in the field, being present at the battles of Chancellorville and Gettysburg, and subsequently took part in General Grant's fighting in Virginia. His talent for organization found ample field in the development of the great field hospitals, with their thousands of wounded and sick. After the war he and others were occupied in creating that monumental record—the great *Medical and Surgical History of the War of the Rebellion*. This work could only be accomplished with the aid of the Government, and this was dispensed to Dr. Billings and his colleagues with a generosity which has enabled them to produce a work than which none other of like magnitude, completeness, and merit exists. It will prove for many years to come, as it has already proved, a treasure-house of information.

A work not less important, and perhaps more after his own heart, has been the making of the Army Medical Museum and Library, at Washington. The museum is really a wonderful thing for its age, both from the quantity and quality of the material arranged in it. It has been now transferred from the old threatre building in which Lincoln was murdered to the palatial structure on the shore of the Potomac, specially built for it under Dr. Billings's direction. Here, too, the wise liberality of the Government is displayed in the completeness of the arrangements and the great expenditure they have entailed. Here, too, are many rooms where, under the supervision of its head, much good work is being accomplished.

It is, we believe not too much to say that the library of the Army Medical Department is the largest and most complete medical library in the world. It, likewise, owes its development to the fostering care of Dr. Billings. It contains not only all the best modern books and periodicals in every language, but a collection of the classic works of every kind connected with medical knowledge of our forefathers in scientific work. Not only is it free to everyone to enter, but to any part of the great United States books from this library are forwarded on application to any duly qualified man. The losses which this entails are stated to be infinitesimal. The crown has recently been placed on another great work fostered by Dr. Billings in the opening of the Johns Hopkins Hospital at Baltimore, built from his plans and under his supervision, an account of which he recently published.

No expense has been spared in the successful attempt to make this the most perfect of modern hospitals.

Amid all this primary official work he has found time for other offices and for the production of books. He has been Vice-President of the National Board of Health. He had charge of the vital statistics of the tenth census, bringing out a report in two large volumes. He has also charge of the vital and mortality and social statistics of cities for the approaching census of the United States.

With all this important occupation Dr. Billings's official rank is less high than is generally supposed in this country. He is Major and Lieutenant-Colonel and Surgeon in the United States Army.

Dr. Billings has also done great service to the whole of the medical profession by his *Index Medicus*, begun in 1879, and still in regular publication. He is now preparing a large dictionary of medical terms, in two volumes, which is to appear speedily.

With such a record, it is not to be wondered that the University of Oxford, wherein all that Dr. Billings has done is well known to Sir Henry Acland, should have deemed him worthy of the high honor of its D.C.L., thus adding his name to those of Owen, Alison, Brodie, Milne Edwards, Van der Hœven, Christison, Stokes, Jenner, Gross, Paget, Lister, Allen Thomson, William Farr, Simon, and others to whom she has given in the last few years her highest degree. Besides this honor, he already holds the honorary degrees of LL.D. Harvard, LL.D. Edinburgh, and M.D. Munich, and he is a member of the National Academy of Sciences in America, which may be in many respects compared to our Royal Society.

How various are the ways by which scientific medicine is being advanced is plain enough to our readers. It is pleasant to think that the United States are advancing along the whole line of knowledge. It is of no small moment that Washington, but lately only a political capital, is becoming a centre of scientific biological effort, through the rapidly expanding National Museum, and the labors of Dr. Billings in the War Office. The probable effects cannot easily be overestimated. The problem of the future of the United States is one of the most interesting, as well as the newest, in the history of the human family. The modern appliances for material growth there seen have never in history been so rapidly developed, and we are glad that a firm grasp is likely to be taken by our American brethren of all of the circumstances that effect the progress of scientific, curative, and preventive medicine.

The Archduke Carl Theodor of Bavaria has been dangerously ill with lymphangitis of the arm and axilla, following inflammation of the hand, due, it is supposed, either to the sting of an insect or to a wound received during an operation. His Highness has now recovered sufficiently to resume surgical practice at Meran. — *British Med. Journal*, June 22, 1889.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JULY 2 TO JULY 15, 1889.

GIBSON, R. J., *Captain and Assistant Surgeon.*—Reports arrival, July 2, 1889, at Camp Lewis, Fisher's Island, New York, in compliance with Par. 5, S. O. 133, Division of the Atlantic, which designated him as Medical Officer for the encampment (rifle practice) at Fisher's Island, New York.

GORGAS, W. C., *Captain and Assistant Surgeon.*—Is granted leave of absence for one month, to take effect on the arrival of a medical officer to relieve him.—Par. 2, *S. O. 84, Headquarters Department of the Missouri*, July 3, 1889.

By direction of the Secretary of War, ANDREW V. CHERBONNIER, *Captain and Medical Storekeeper*, will, in addition to his present duties, take charge of the office and perform the duties of Acting Assistant Medical Purveyor in St. Louis, Missouri, during the absence of Captain George T. Beall, Medical Storekeeper.—Par. 2, *S. O. 151, A. G. O.*, July 2, 1889.

By direction of the Acting Secretary of War, the retirement from active service this date, by operation of law, of THOMAS A. MCPARLIN, *Colonel and Surgeon*, under the provisions of the Act of Congress approved June 30, 1882, is announced. Colonel McParlin will repair to his home.—Par. 2, *S. O. 157, A. G. O.*, July 10, 1889.

TOWN, FRANCIS L., *Lieutenant-Colonel and Surgeon.*—Promoted Surgeon, with rank of Lieutenant-Colonel, to rank from July 10, 1889, vice A. K. Smith, promoted.

SMITH, ANDREW K., *Colonel and Surgeon.*—Promoted Surgeon, with rank of Colonel, to rank from July 10, 1889, vice McParlin, retired.

PERLEY, H. O., *Captain and Assistant Surgeon.*—Is ordered to accompany troops from Fort Wayne, Michigan, to Gognac Lake, Michigan, to encamp there with the Michigan State troops, from August 8 to 13, 1889.—Par. 1, *S. O. 154, Headquarters Division of the Atlantic*, July 9, 1889.

PERLEY, H. O., *Captain and Assistant Surgeon.*—Is granted fourteen days leave of absence, to commence about July 14, 1889.—Par. 2, *S. O. 154, Headquarters Department of the Atlantic*, July 9, 1889.

BRECHEMIN, LOUIS, *Captain and Assistant Surgeon.*—Ordered to the Illinois National Guard, near Springfield, Illinois, during the remaining portion of the encampment.—Par. 1, *S. O. 159, A. G. O.*, July 12, 1889.

BALL, R. R., *First Lieutenant and Assistant Surgeon.*—Is granted leave of absence for fifteen days.—Par. 3, *S. O. 87, Department of the Missouri*, July 9, 1889.

INES, F. J., *Assistant Surgeon.*—Now at Fort Lyon, Colorado, will proceed to camp near Oklahoma City, Indian Territory, and report to the commanding officer for duty, relieving W. C. Gorgas, Captain and Assistant Surgeon, who, when so relieved, is authorized to avail himself of the leave of absence granted him in Par. 2, S. O. 84, *c. s.*, Department of the Missouri.—Par. 1, *S. O. 87, Department of the Missouri*, July 9, 1889.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE TWO WEEKS ENDING JULY 13, 1889.

WHITE, S. STUART, *Assistant Surgeon.*—Ordered to the Naval Hospital, Brooklyn, New York.

WHITE, C. H., *Medical Inspector.* — Detached from the "Trenton," and wait orders.

NORFLEET, ERNEST, *Passed Assistant Surgeon.*—Detached from the "Trenton," and ordered to the "Monocacy."

AMES, H. E., *Passed Assistant Surgeon.*—Detached from the "Monocacy," proceed home, and wait orders.

HARMON, G. E. H., *Surgeon.*—Detached from the "Constellation," and ordered to the Naval Academy.

LOWNDES, C. H. T., *Assistant Surgeon.*—Detached from the "Constellation," and ordered to the Naval Academy.

HARVEY, H. P., *Surgeon.*—Detached from the "Vandalia" July 7th, proceed home, and wait orders.

WHITE, S. STUART, *Assistant Surgeon.*—Detached from the "Trenton" July 7, 1889.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LV. SATURDAY, JULY 27, 1889. No. 4.

ORIGINAL ARTICLES.

THE MORTALITY OF ACUTE LOBAR PNEUMONIA,

From a Study of All the Cases of this Disease Treated at the Massachusetts General Hospital from the First Case, in 1822, up to the Present Day.[1]

BY C. W. TOWNSEND, M.D.,
AND
A. COOLIDGE, JR., M.D.,
OF BOSTON.

THAT acute lobar pneumonia is treated to-day far differently than was the same disease fifty years ago is a well-known fact. Has there been any change in the mortality for the better or worse; and, if so, is this change due to the treatment alone, or is it dependent rather on the changed conditions of life and constitution of the patient, or is it due to any change in the nature of the disease itself?

These and similar questions present themselves, and cannot be answered by a superficial examination of mortality statistics, but demand a thorough examination of the individual cases. To make entirely plain what is meant by this statement, let us illustrate by the following example: Suppose ten patients sick with pneumonia were treated every year at a hospital, and that in the year 1860, of these ten patients, two were over sixty years of age, two were hard drinkers, and two had organic disease of the heart; while in the year 1880 nearly all the pneumonia patients happened to be healthy young adults, an entire change in the treatment having at the same time taken place. It is evident that the death-rate in these two years would be very different, a difference which a superficial observer might claim to be due to the change in therapeutics. But if, instead of merely examining the list of diseases and results, he had examined the record of each case, it is possible he would have come to a far different conclusion.

At the suggestion of Dr. H. I. Bowditch and of Dr. F. C. Shattuck, and with the permission of the resident physician, Dr. J. W. Pratt, the writers have examined the records of the Massachusetts General Hospital from its first books in 1821 to the present time (May 1, 1889), for the purpose of throwing some light, if possible, on these questions.

But before considering the results, it may be well to review briefly some of the papers which have recently appeared discussing the same subject from data obtained from other hospitals. Dr. Hartshorne, in a paper read before the College of Physicians of Philadelphia, in February, 1888, apparently succeeded in demonstrating that the mortality from pneumonia has greatly increased. In the quarter of a century prior to 1858, he finds from a large number of statistics of cases reported by Skoda, Balfour, Dietl, from the British and United States armies, from European hospitals, and from the Pennsylvania Hospital, that the mortality from acute pneumonia was only 8⅓ per cent. This certainly contrasts in a striking way with the present mortality, which was found by the Collective Investigation Committee,[1] in an analysis of 1066 cases, to be 18 per cent., and which Dr. Hartshorne has found to be stated at about 25 per cent., or more, in the large general hospitals in this country. He thinks that the disease is now practically the same as it was forty or fifty years ago, and that the increase in mortality is due to the change in treatment. To show the great evils of opium, Dr. Hartshorne gives such statistics—among others—as the following: One case in 12.56 died where the treatment consisted of bleeding and the use of tartar emetic; while where opium without bleeding was used, as many as 1 case in 3.3 died. Such statistics, it seems to us, are worse than valueless, for not one word is said as to whether the cases were old or young, feeble or strong, debilitated by alcoholic habits or not; neither do they take into consideration a possible variation in the severity of the disease, a fact which is generally recognized in the study of other specific diseases.

Dr. William Osler[2] gives a striking illustration of the worthlessness of statistics taken without such analysis for the purpose of defending a theory, by figures taken from the same hospital (Pennsylvania Hospital), for a different series of years, which, far from showing, as do Dr. Hartshorne's figures, that the mortality has increased, show that it has, if anything, been reduced, as will be seen by these figures:

DR. HARTSHORNE'S STATISTICS.		DR. OSLER'S STATISTICS.	
Years.	Mortality.	Years.	Mortality.
1845–'47	6.25 per cent.	1848–'50	37.9 per cent.
1865–'67	18.50 "	1858–'60	21.2 "
1884–'86	31.00 "	1868–'70	22.8 "
		1878–'80	32.7 "

Of 704 cases treated at the Pennsylvania Hospital since 1845, Dr. Osler finds a mortality of 29.1 per cent.

[1] Read before the American Climatological Association, June 24, 1889.

[1] The Collec. Invest. Record, vol. ii., July, 1884.

[2] University Medical Magazine, November, 1888.

Dr. Osler also gives, without special analysis, the mortality of the Montreal General Hospital and the Charity Hospital of New Orleans, as follows:

MONTREAL GENERAL HOSPITAL.		CHARITY HOSPITAL, N. ORLEANS.	
Years.	Mortality.	Years.	Mortality.
1853–'63	16.2 per cent.	1830–'39	44.6 per cent.
1863–'73	16.1 "	1840–'49	35.3 "
1873–'83	23.7 "	1850–'59	32.2 "
1883–'87	20.3 "	1860–'69	43.9 "
		1870–'79	40.2 "

Out of a total of 1012 cases at the Montreal Hospital, since 1853, there was a mortality of 20.4 per cent.; of 3969 cases treated at the New Orleans Hospital, 38.01 per cent. were fatal. The increasing death-rate from north to south, as illustrated by these hospitals, is interesting.

Osler also gives figures from the Edinburgh Infirmary as follows:

Before 1848, mortality in 567 cases . .	36.3 per cent.
1848–1856, " " 611 " . .	21.2 "
1856 upwards, " " 548 " . .	12.7 "

A further analysis of these cases might show that this decrease in death-rate was deceptive.

Dr. Gouverneur Smith,[1] in a recent article, says that the lowest mortality from pneumonia, at the New York Hospital, occurred in the decade between 1820 and 1830; that the mortality has been rising since then, and has during the last decade reached its acme, considerably over double the earlier percentage. As he truly remarks, however: "Hospital statistics, in order to afford valuable scientific data, must be sifted and classified in groups of cases." He then goes on to say: "Without any such general and accurate figures to guide us relating either to hospital or private practice in this country, but from such sources of inference as are at hand, and from observation, it is now an accepted fact that the death-rate from pneumonia is much greater at present than it has been hitherto." This, to say the least, is a very sweeping assertion.

Recognizing the great danger of fallacious reasoning from hospital statistics, the writers have endeavored, with minds freed as much as possible from preconceived ideas, to analyze each case of acute lobar pneumonia that has been entered in the record books of the Massachusetts General Hospital. In the earlier years the table of diagnoses in the end of each record book was found to be often unreliable, and they were obliged to make their own diagnosis directly from the records. Thus, before 1830, clear cases of acute lobar pneumonia were often found among the diseases entered as "empresma pleuritis," all of which, therefore, had to be examined for this purpose. On the other hand, cases entered as pneumonia, or "empresma pneumonitis," in these earlier days were often clearly cases of broncho-pneumonia or of phthisis. It is evident, therefore, that statistics drawn up from the list of cases of pneumonia as entered in the table at the end of each record book would show very different results in the earlier years from those we have obtained by a decidedly longer process.

Added to these difficulties was the fact which one can hardly realize now in the day of careful record of physical signs, namely, that before November, 1864, there is no record of the temperature of the patient, and the first temperature chart was made in February, 1867, but these charts did not come into regular use until several years later. Then, too, in the earlier days, examinations with the stethoscope were first coming to be practised, and were entered in the record book as if they were a great curiosity, as these records certainly are now. In cases entered before 1835 there was often no record of physical signs, and we were obliged to infer the seat of the lung lesion from the description of the symptoms. The prolixity of the earlier records, extending over a number of pages, and the unmethodical and, as compared with recent records, unscientific manner of recording facts is very striking. It is often said that as we depend at the present day so much on the observation of instruments of precision, like the thermometer, we neglect to observe the patient; but the writers were both impressed with the abundance in the earlier records of unessential details, and the absence oftentimes of important symptoms and phenomena which should have been noted.

After these introductory and explanatory remarks let us examine the cases.

The Massachusetts General Hospital was opened for patients in 1821, and from January, 1822, when the first case of acute lobar pneumonia was admitted, up to the present time, May 1, 1889,[1] exactly one thousand cases of this disease are to be found in the records of the hospital. Of this number, two hundred and fifty were fatal, or exactly twenty-five per cent. of all cases.

The following table shows the total number of medical cases in the hospital for each year, also the number of cases of pneumonia and the number of deaths among the latter.

As until very recently the total number of cases each year was too few from which to draw conclusions of any value, we have divided the figures into periods of ten years, making seven decades in all from 1822 to 1889.

[1] Medical Record, October 20, 1888.

[1] The writers were obliged to wait till this late date, May 1, in order to obtain just one thousand cases. It may be remarked here that the writers examined independently alternate volumes of the records, and were interested to find how closely their number and percentages corresponded.

TABLE SHOWING NUMBER OF MEDICAL PATIENTS AND OF CASES OF PNEUMONIA IN THE MASSACHUSETTS GENERAL HOSPITAL FOR EACH YEAR.

Year.	Number of medical patients.	Cases of pneumonia.		Year.	Number of medical patients.	Cases of pneumonia.	
		Total.	Died.			Total.	Died.
1822	67	2	1	1857	418	7	1

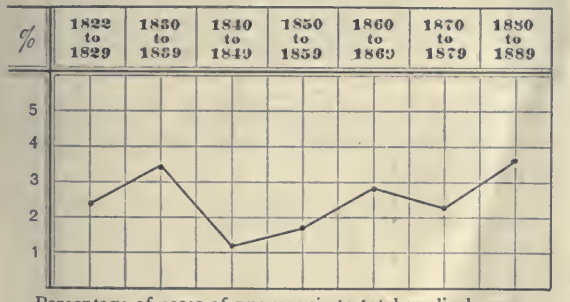
1856	440	8	4	May 1			

Incidentally, we find a very varying proportion between the number of cases of pneumonia and the total admissions as shown by Chart 1.

CHART I.

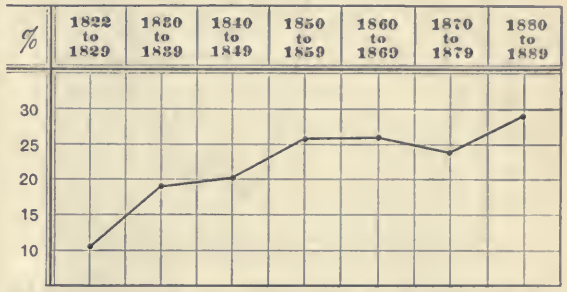


Percentage of cases of pneumonia to total medical cases, in decades.

It will be seen that in the last decade a proportionately larger number of cases of pneumonia have been admitted. It is hardly fair to conclude from this, however, that pneumonia has become more prevalent, as we must remember that with the modern ambulance system many very sick patients are taken to the hospital, while in former years the absence of this system would prevent many who were taken sick with this disease of sudden onset from receiving hospital care. In the 1830 decade, however, nearly as large a percentage of pneumonia cases were admitted to the hospital, while the lowest percentage occurred in the '40's.

A glance at the table giving the cases and mortality in each year shows great variations; in some years no deaths having occurred from pneumonia, in other years a large proportion were fatal. Arranged in decades and represented graphically we obtain the following chart:

CHART II.



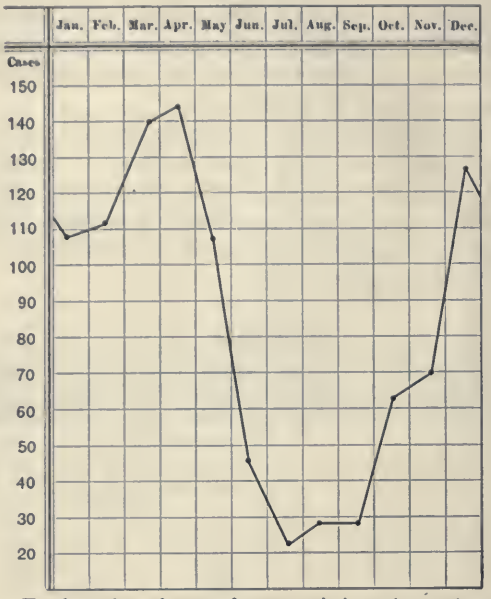
Percentage of deaths from pneumonia to all cases of pneumonia, in decades.

This shows an almost unbroken rise in the mortality from ten per cent. in the 1820 decade to twenty-eight per cent. in the present decade. From this we might infer that pneumonia is much more fatal now than it was fifty years ago, and much more fatal fifty years ago than it was seventy years ago, and that its fatality is steadily increasing—a conclusion well calculated to alarm and depress us.

As we have urged in the introductory part of this paper, conclusions like this should not be drawn until we have examined each individual case, else we may be entirely misled. We all know that the treatment of pneumonia, as of other diseases, has radically changed during the period of years we are considering, but before appealing to this factor as a cause of the change in mortality, let us examine the other factors, which perhaps may partly or entirely be the cause.

We have noted in each case the age, sex, race, previous condition, whether healthy or delicate, whether temperate or intemperate in the use of alcohol, and also the presence or absence of complications. All these are factors of more or less importance in their relation to the mortality. We have also noted the month of the year and the site of the lesion of the lung, together with the duration of the fever, till death or recovery, and the length of stay in the hospital. The month of the year and the site of the lung lesion, although having but little bearing on the present discussion, are of interest for statistical purposes, and are, therefore, recorded here in the following table and chart:

CHART III.



Total number of cases of pneumonia in each month.

A comparison of this chart with one prepared by one of the writers[1] from an analysis of 412 cases occurring at the Massachusetts General Hospital between 1870 and 1885, shows a great similarity. We calculated the per cent. fatal in each month, but from the irregularity of the results concluded that they were of no significance.

TABLE SHOWING PORTIONS OF LUNG INVOLVED IN ORDER OF FREQUENCY.

Seat of lesion	Total.	Died.	Per ct. fatal.
Lower right lobe	337	47	14
Lower left lobe	216	28	13
Both lungs	111	63	57
Upper right lobe	105	25	24
Whole right lung	74	39	53
Whole left lung	39	26	67
Upper left lobe	31	7	23
Middle right lobe	19	4	22

We determined the day of death in all the fatal cases, where this was possible, and found, as shown by the following table, that the eighth day was the one on which most deaths occurred.

Of 212 occurring between 1870 and 1885, 128 cases ended by crisis and 84 by lysis.

Of the two sexes, there were 724 males and 276 females, of which 182, or 25 + per cent. of the former, while 68, or 25 — per cent. of the latter were fatal. The great preponderance of males, about four times as many, is due to the fact that in early years there were, we believe, larger accommodations for male than female patients, and, as a rule, men with acute diseases are perhaps more likely to be taken to a hospital than women. The British collective statistics from private practice show, however, a similar but not as great disproportion between the two sexes; they record about twice as many males as females. As the mortality in the two sexes was in our cases the same, although usually stated to be higher in females, the factor of sex is excluded in our search for the cause of the increase in the fatality of the disease.

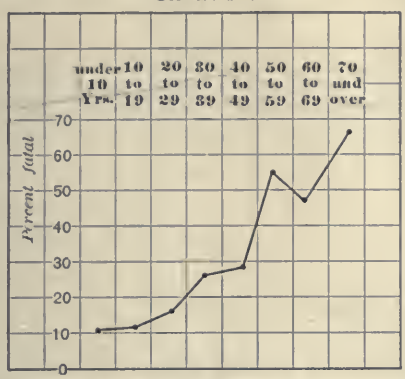
The factor of age is, however, one of great importance, as shown by the following table, and graphically by Chart IV.

Age of patient.	Total cases.	Fatal.	Per ct. fatal.
Under 10 years	10	1	10.0
10 to 19 "	113	12	10.6
20 " 29 "	373	69	18.5
30 " 39 "	217	55	25.3
40 " 49 "	136	40	29.2
50 " 59 "	80	44	55.0
60 " 69 "	32	15	46.9
Over 70 "	12	8	66.7

It will be seen that up to the age of 49 years the mortality gradually increases from 10 per cent. to 29 per cent. After this age it makes a sudden jump of over 20, and rapidly rises above 50 per cent. As only ten cases occurred under 10 years of age, it is hardly fair to lay much value on this mortality rate of 10 per cent., which is probably too high. The

only fatal case in this class was a child 2½ years old, emaciated and enfeebled from previous neglect and bad treatment.

CHART IV.

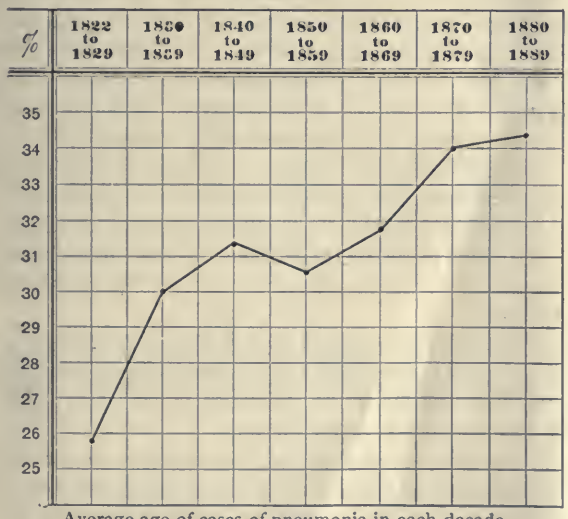


Mortality at different ages.

The break in the rising line of mortality in those between 60 and 69 years of age may be explained by the fact that 60 per cent. of these patients happened to be neither complicated nor intemperate, while of those between 50 and 59 years of age only 55·5 per cent. were free from complication or intemperance. A similar chart in the analysis of 412 cases previously referred to, corresponds almost exactly with Chart IV, but the fall at 60 years does not occur.

Now, an examination of the hospital records shows not only a proportionately greater number of patients over 50 years of age in the latter decades, but the average age, as will be seen by Chart V., has steadily increased from 25½ years in the '20 decade to 34½ years in the '80 decade.

CHART V.



Average age of cases of pneumonia in each decade.

Here, then, is one cause at least for the higher death-rate in later years, and one which is, of course, entirely independent of treatment.

A complete record of the condition of the patient previous to the attack of pneumonia would be of great value, but, unfortunately, was not kept in many of the cases. 445 of the patients were stated to have been healthy; of these, 62 died, or 14 per cent., a percentage considerably under the average. 67 were stated to have been delicate, no especial disease existing; of these, 26 died, or 39 per cent. 161 had acute or chronic complications, and of these, 59 died, or 37 per cent. The complications, with the number of deaths in each, are given in the following table:

TABLE OF DISEASES COMPLICATING PNEUMONIA.

Disease.	Total cases.	Number fatal.
Asthma	6	4
Bleeder	1	0

Typhoid fever	22	10
Total complications	193	85
Counted twice	32	26
Total patients with complications	161	59

55 were recorded as temperate in the use of alcohol, of whom 8 died, or 15 per cent., while 109 were intemperate, and 45 died, or a mortality of 41 per cent.

The influence which the presence or absence of complications, of good health and of temperance have on the mortality of acute pneumonia is a fact well recognized, and is duly emphasized by the above analysis. We must next find whether complications and intemperance are more or less prevalent among pneumonia patients at the hospital now than they were in former times.

An objection will undoubtedly be raised here that in former days complications were not so readily recognized as at present, and that particularly in post-mortem examinations the pathologist almost always finds some abnormal conditions which were passed over in silence because not recognized in the older records. Therefore, we should expect to find complications more prevalent in later years. As we felt the danger of this, we think we have avoided it by recording only those cases as complicated where the diagnosis was plain, and where the lesion, if observed post-mortem, was a gross one, and one that was as easily recognized by early as by late reporters. We think all will admit this on examining the list of complications. The complication emphysema, it seemed to us, might be rather too fine a diagnosis for our list, but of the two cases one occurred in the '30 decade and one in the '80 decade, so this certainly ought to remain. Pericarditis, another example, occurred once in the '30, once in the '60, and again in the '80 decade.

Diarrhœa is entered in our list, but only the very severe and generally chronic cases are there mentioned, for a slight or moderate diarrhœa is, as is well known, a not infrequent symptom in pneumonia.

Many of the complications, as will be seen, are chronic, antedating the attack of pneumonia, while the rest, with but few exceptions, although acute, are entirely accidental and independent of the pneumonia. The exceptions, gangrene of the lung, empyema, and in some cases pleural effusion, being a part, as it were, of the pneumonia, should perhaps have been excluded, as it may be said that their occurrence may have been due to the treatment; but these cases are so few in comparison with the others, and are so evenly distributed through the decades, that they will not influence the results.

The following table shows the number of cases that were complicated or simply delicate, and the number intemperate in each decade.

	1822 to 1829.	1830 to 1839.	1840 to 1849.	1850 to 1839.	1860 to 1869	1870 to 1879.	1880 to 1889.
Complicated or delicate,	6	11	6	15	39	37	114
Intemperate,	0	2	2	8	18	12	66

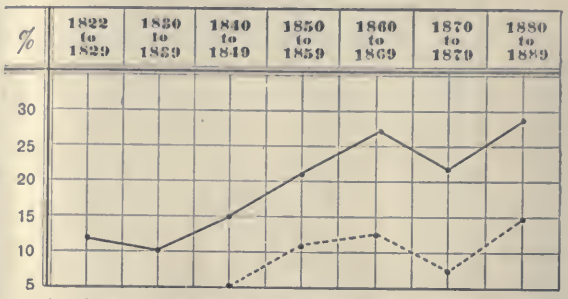
Calculating the percentage of these cases to the total number of cases of pneumonia, we find that this percentage, both of the complicated and delicate and of the intemperate, has been increasing, as shown by Chart VI.

The only remaining factor is that of race, and our 1000 cases are divided as follows:

	Total cases.	Fatal.	Per ct. fatal.
American (including Canadians)	463	103	22
Irish	371	94	25
Other foreigners	119	36	30
Not recorded	47	17	36
Total	1000	250	Aver. 25

This table shows the least fatality among the Americans, a greater fatality among the Irish, and a still greater one among other nations; but we have no right to infer that the race factor itself is the

CHART VI.



Ratio of the complicated and delicate cases to total number of cases of pneumonia, represented thus.—— Ratio of intemperate cases to total number, thus. . . . .

cause of this difference. Patients of foreign birth who are taken to the hospital are perhaps of greater age, or more liable to have complications or to be intemperate than those of American birth, and these factors may account for the difference in mortality. It occurred to us, therefore, that it would be interesting to see what the percentage of mortality would be in the different races, omitting all those fatal ones who were over fifty years of age who were intemperate, delicate, or complicated, factors which we have shown are sufficient cause for a large mortality. The results obtained are as follows: Americans, 9 per cent. fatal; Irish, 11 per cent. fatal; other foreigners, 14 per cent. fatal. Comparing these percentages with the former ones, we find that the proportionate mortality of the different races remains almost as before, with the exception that Americans are even more favored than by the first analysis, while among foreigners, with the exception of the Irish, the mortality is proportionately greater than before. The reason of this may be that our most poorly nourished classes are largely foreigners.

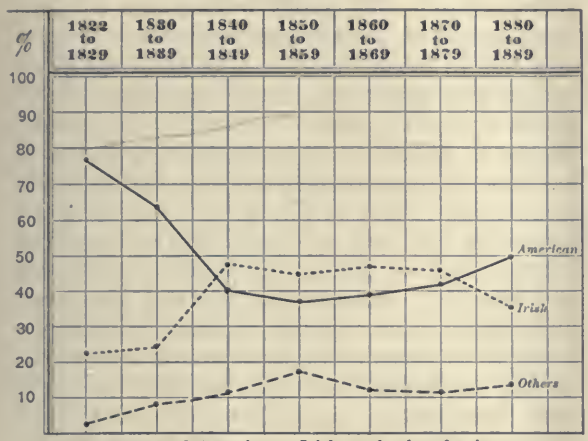
During the early part of the century American patients were, of course, more abundant, relatively, than they are now; a fact which is shown by Chart VII., which gives the percentages of the three classes among the pneumonia patients in the hospital by decades.

From the descriptions of the disease contained in the records there seems to be no reason for thinking that the character of pneumonia has susceptibly changed in this series of years.

To sum up the results of the analysis, so far, we may say that the sex of the patient has in these cases no influence on the mortality; that the age of the patient is of great significance—the older the patient the greater the mortality; and that over the age of fifty years more than fifty per cent. die; that intemperate patients are far more apt to die than tem-

perate patients; and that the mortality in the patients who are delicate or who have some complication is much higher than in the healthy and non-compli-

CHART VII.



Percentage of Americans, Irish, and other foreigners, by decades.

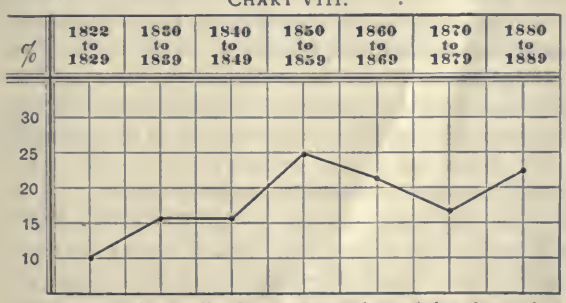
cated; and, finally, that the proportion of deaths among Americans is less than among Irish, and in these latter less than among other foreign nations, and that this difference is not dependent as far as our studies show, on the existence of more frequent complications or intemperance among foreigners.

We have also seen that the average age of the pneumonia patients has been steadily increasing from the earliest decades of the hospital to the present day; that the relative number of intemperate and of delicate patients has increased, and also of cases complicated by other diseases, and, finally, we have seen that the proportion of foreign-born patients has also increased.

Let us see how much influence each of these factors has had in increasing the mortality from pneumonia in the hospital, and whether it is possible that all of them together may not be the whole cause, and that it will not be necessary, as might have been our first impulse, to appeal to the change of treatment as the cause of this increase in the mortality.

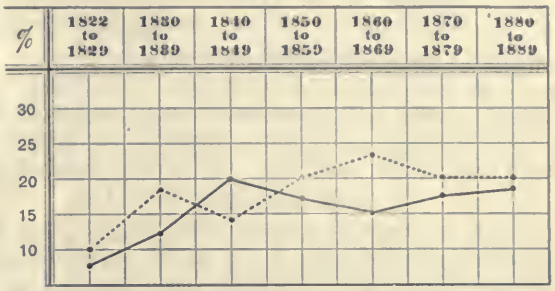
In order to learn the answer to these questions we have prepared the following charts which we think explain themselves:

CHART VIII.



Percentage of mortality from pneumonia, omitting those who died over fifty years of age, by decades.

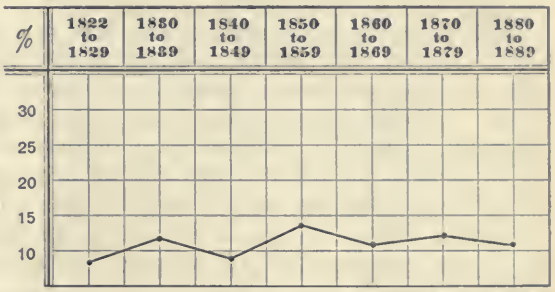
CHART IX.



Mortality, omitting the delicate and complicated who died, represented thus ————

Mortality omitting the intemperate who died thus .....

CHART X.



Mortality by decades, omitting all fatal ones who were over fifty years of age, or were delicate, complicated, or intemperate.

This last chart represents, then, the mortality in the hospital by decades, excluding all cases whose death can reasonably be accounted for, that is to say, all who died who were over fifty years of age, were intemperate, delicate, or who had complications. As will be seen, instead of showing as in Chart II., a regular and decided increase in the mortality from the earlier part of the century to the present day, it shows but little variation from decade to decade, and we certainly could not infer from this chart that the mortality from pneumonia had on the whole changed in the last sixty-eight years.[1]

We must conclude, therefore, that, as shown by this analysis, the mortality of acute lobar pneumonia at the Massachusetts General Hospital has remained practically the same from 1822 to 1889, notwithstanding the great changes in treatment, and that the disease is the same now as it was sixty-eight years ago. This result, although not very encouraging, is certainly far better than was the hasty conclusion drawn from the mortality table alone before analyzing the cases.

But are we to infer that treatment is of no avail? Has it not had any influence on the duration of the disease or of the convalescence, and how has the general condition of the patient in these two stages

[1] It is probable if we had taken into consideration the increase in foreigners and the decrease in Americans of late years, that Chart X. would have been more nearly a horizontal line than it is now.

been influenced by the treatment? A short *résumé* of the treatment at different periods is necessary before we can answer these questions.

Prior to the year 1850 the treatment was truly heroic; almost every case was vomited and purged, given mercury to salivation and sore gums, blistered with cantharides, and bled. Of the 187 cases before 1850, 115 or nearly two-thirds were bled. The quantity of blood taken was often large. In 1833 one case was bled three times to the total amount of fifty ounces, and forty-eight leeches in all were applied during his illness. Another case was bled during his illness sixty ounces, or nearly two quarts. Local wet-cupping and leeching at the same time with venesection were also used.

The diet in this period was a low one, as can be seen by the following examples taken from the records: "May have juice of quarter of an orange at a time." "May have a teacup of milk three times daily with cracker." "May have broth not exceeding four ounces and repeat in four hours if he wants it." This low diet was also continued into the convalescence. Thus, in 1849, a patient on the fifth day of the convalescence was allowed "Broth six ounces at noon."

In the '40's mercury and emetics were less frequently used, but the patient was still given tartrate of antimony and kept on the verge of vomiting. Blisters at this time were also gradually omitted and replaced by sinapisms.

Cantharides, besides producing much local effect, was a frequent cause of strangury, so that catheterization had to be resorted to. The sores made by the blister were irritated by various drugs in order to obtain a more intense effect, so that gangrenous sloughs and ulcers slow in healing were not infrequent results. During the convalescence such records as these were not uncommon: "Complains of nothing but ulcer left from blistering." "The black slough from the blister beginning to separate."

Cathartics were given freely, not only in the hospital but before their arrival there. One case, a man of twenty-three years, was said to have had fifty dejections on the third day of the disease after taking cathartics at his home, and it seems as if the fatal result might be attributed to this.

Before 1850, opium was scarcely ever used, and in no case was the treatment an expectant one. The occasional use of colchicum and other drugs was noticed. Stimulants during the period before 1850 were almost never given, and then only in minute quantities, generally just before death. For example, one of the earliest mentions of its use is in 1839, when the following record occurs: "May have a tablespoonful of cider." In another case: "Wine whey if skin becomes cold;" this was given a few hours before the patient's death. As another example, may be mentioned a patient forty-four years of age with a complicating pericarditis and the history of a cough for ten years, who was kept on a low diet, was bled, vomited, purged, and blistered, and was not given any alcohol. The patient died.

From 1850 to 1860 seems to have been a transitional period in the hospital treatment of this disease, and for the first time we meet with cases which were treated practically in an expectant manner, 11 out of 72 cases being so treated in this decade. Opium in occasional moderate doses, generally in the form of Dover's powder, was then used for nearly the first time; syrup of Tolu and "fever mixtures" containing nitre were also given, and an occasional administration of quinine and veratrum viride was also noticed. Less than one-third (19 cases) were bled, and the other heroic measures were proportionately decreased. Alcohol was used more frequently just before death, but the fear of giving it while there was fever is evident from such a record as this in 1858: "May have cider ℥vj or ℥viij in the twenty-four hours if no more fever."

Soon after 1860, the records show that pneumonia patients were being systematically fed with milk and broths. Heroic treatment became a thing of the past, emetics, cathartics, mercury, and blisters being discarded, and there are records of but six cases of venesection after the year 1860, and leeches were used in only a very few. Alcohol was given systematically from this time. Of 741 cases treated since 1860 there is record of the use of alcohol in 353 cases. A comparison of the mortality of those to whom stimulants were given and those treated without them would be useless, for the more severe and feeble cases were given alcohol, and nearly all received it before death.

The treatment by drugs was slight after 1860. In the 60's and early in the 70's wine of ipecacuanha in small doses was largely used. After 1875 carbonate of ammonium was the drug most frequently prescribed. Opium was given in many of the cases, generally in moderation, to relieve pain. Digitalis was also used to some extent. There are but very few records of quinine in the large doses sometimes used in New York and elsewhere. In the last few years antipyrin and acetanilid have been used in a few cases, but we may say that, as a rule, since 1860 the treatment of pneumonia at the hospital has been largely sustaining and expectant.

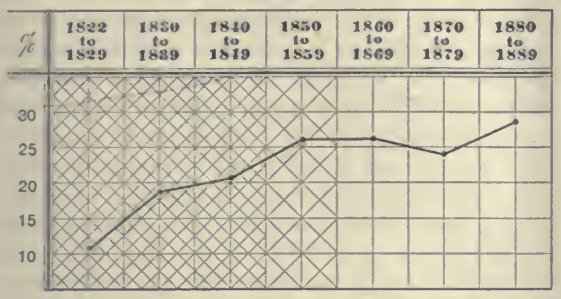
A glance at Chart XI., which is the same as Chart II., but shaded to indicate the periods of different treatment, shows that the entire rise in the mortality took place during the period prior to 1860, when the treatment was entirely or partly heroic.

This fact alone, even if we had not demonstrated the same truth by another method, shows the entire lack of connection between the mortality rate and the method of treatment.

Is it possible that the heroic treatment contained

both bad and good elements, which by counteracting each other, gave, as we have seen, exactly the same results as by the expectant method; and, therefore, if the bad elements were eliminated we

CHART XI.



Same as Chart II., also showing periods of treatment. Before 1850 heroic; between 1850 and 1860 transitional; after 1860 expectant.

should have better results than by the expectant method? In the light of our present knowledge of the bacterial nature of the disease, is it possible that the germicidal mercurial treatment constituted the good element?

After this digression let us now answer the questions as to the duration of the disease and of its convalescence as affected by treatment. We obtained the average duration of the fever and found it to vary in each decade but a small fraction from nine days. The duration of the convalescence also, as shown by the length of stay in the hospital, has not changed, for in each decade the average stay of each patient varied but very little from three weeks and four days.[1]

One more point is of interest. Did the aged and delicate, the complicated and the intemperate have as good a chance for recovery under the old heroic treatment as with the later sustaining one?

Counting all the cases of these classes together, which means that many are counted twice, we find before the year 1860, or during the heroic period, 62 cases among these classes, with 25 deaths, and after 1860 397 cases, with 165 deaths. Reduced to percentage, we find the mortality to be almost exactly the same, namely, 40 per cent. in the first period and 41 per cent. in the second period.

We must, however, admit that the present treatment of expectancy, a treatment which makes the patient as comfortable as possible, preserves his strength and avoids everything harsh, is certainly far more agreeable to the patient than the former heroic method.

After these studies we cannot but admire the regular and uniform manner in which pneumonia—that type of self-limited diseases—has run its course in all these years uninfluenced by the varying treatment it has received.

SUMMARY.

1. In the 1000 cases of acute lobar pneumonia treated at the Massachusetts General Hospital from 1822 to 1889, there was a mortality of 25 per cent.

2. The mortality has gradually increased from 10 per cent. in the first decade to 28 per cent. in the present decade.

3. This increase is deceptive for the following reasons, all of which were shown to be a cause of a large mortality:

(*a*) The average age of the patients has been increasing from the first to the last decade.

(*b*) The relative number of complicated and delicate cases has increased.

(*c*) The relative number of intemperate cases has increased.

(*d*) The relative number of foreigners has increased.

4. These causes are sufficient to explain the entire rise in the mortality.

5. Treatment, which was heroic before 1850, transitional between 1850 and 1860, and expectant and sustaining since 1860, has not, therefore, influenced the mortality rate.

6. Treatment has not influenced the duration of the disease or of its convalescence.

[1] The table shows the average duration of fever and stay in the hospital in each decade.

ON SOME MODIFICATIONS IN THE TECHNIQUE OF ABDOMINAL SURGERY, LIMITING THE USE OF THE LIGATURE EN MASSE.[1]

BY LEWIS A. STIMSON, M.D.,
OF NEW YORK.

THE period during which the important and brilliant operations, now so frequently and successfully performed within the abdominal cavity, have been practised is relatively very brief, and although the accumulated, and, in many instances, the individual experience is large, the work has, in the main, been done along lines and according to methods and principles which, it may be assumed, have yet to undergo modifications that will be slowly evolved from the thoughts and experience of successive generations of surgeons. In this respect abdominal surgery differs widely from the other branches of the art: it can profit, not by the experience of centuries within its own field, but by that of only a few decades of years; and as, in addition, the material conditions of this field present wide variations from those of the regions upon which the skill and thought

[1] Read before the American Surgical Association, 1889.

of surgeons have heretofore been concentrated, it is not singular that corresponding differences should appear in its operative principles and methods. Of these differences the most striking is in the measures taken to prevent or arrest hemorrhage, which consist, as a rule, of *ligatures en masse*, ligatures of heavy silk, each embracing a large mass of tissue, and thus creating one or more "stumps" from which the blood-supply has been cut off, and which, subsequently, are either fixed in the external wound to be slowly cast off, or are left in the abdominal cavity to undergo molecular disintegration and absorption.

The advantages which, in theory at least, belong to this method are celerity of performance and freedom from hemorrhage, and it is not to be denied that in many cases, and especially in those which were the first undertaken in this branch, and success in which led to the great extension that has followed —the removal of narrow pedunculated cysts of the ovary—these advantages do exist. By no other method of treatment, probably, could the cyst be removed through so small an incision, so rapidly and so safely, and it is not strange that its admirable adaptability to these cases should have led to its habitual use in others, and that the attention and ingenuity of operators should have been directed by its defects to its improvement and modification rather to the substitution of a radically different method.

The principal objections to the *ligature en masse* are two in number: (1) It is not always an efficient protection against hemorrhage, and (2) the mass of tissue embraced by it and forming the stump is sometimes so large or so related that it cannot safely be returned within the cavity and treated intra-peritoneally, but must be fixed in the parietal wound to be cast off as a slough, and thus to necessitate healing by granulation, with its delay and risks. The size of the stump is not the only reason for treating it extra-peritoneally; another and equally strong one arises from the fear of hemorrhage or from the nature of the means used to prevent it, such as the elastic ligature, the clamp, or the écraseur, which cannot be left within the peritoneal cavity. The danger of hemorrhage from a stump that is long enough to be treated extra-peritoneally is not great, for the protective means at our disposal are efficient, and, if bleeding should occur, it can be promptly detected and readily controlled. But it is vastly different with ligatures that are left within the cavity, ligatures of silk or catgut embracing, usually, a broad layer of parietal peritoneum that has been drawn in from all sides toward the ligature and is retained by it under considerable tension. Within this puckered fold of peritoneum lie the vessels and the tissue in which they are imbedded, all tense because they have been lifted up and drawn upon in the application of the ligature, and all constantly solicited by this tension to slip out of the loop. Each slight yielding to this traction makes the next one easier, for it diminishes the amount of tissue embraced within the loop, and thus diminishes also the friction by which the rest is retained. Hemorrhage from such a ligature is not uncommon, and has been fatal, and the post-mortem examination plainly shows the mechanism by which it has been made possible; there is the large circular gap in the peritoneum, the wide extravasation in the subperitoneal connective tissue, and far up within it the divided vessel, all indicating by their separation the traction necessary to bring them within the loop of a single ligature. The fault is not in the tying of the ligature; it has not become untied, but it has failed to hold, just as it would have failed if it had been placed upon a smooth, hard cone. The ligature has not simply to compress the vessels contained within it, but it has also to oppose a constantly exerted everting strain, acting toward all sides, widening its loop, and favoring the escape of the central vessels by loosening the friction upon them, and in this contest it has too often proved the weaker.

The consideration that appears to have had most to do with the general use of this dangerous form of ligature is the supposed necessity of tying all divided tissues in order that all hemorrhage may be prevented, not only that from the larger vessels, but also that from the minute vessels of the peritoneum and connective tissue. But this necessity, I think, does not exist, and this mode of ligature should be abandoned, except in certain special cases, for that which is the rule in operations upon other parts of the body, the ligature of the arteries alone with the smallest possible amount of additional tissue, and every effort should be made to exclude the peritoneum itself from the grasp of the ligature. Ordinarily, this is not difficult to accomplish. Take, for example, the outer portion of the broad ligament, where its peritoneal layers are reflected forward, backward, and outward, over the pelvis, and where the bundle of ovarian vessels lies. Draw it well up by lifting the ovary, place a rather long-bladed pair of self-holding forceps transversely upon it close to its base, divide the ligament a half inch on the distal side of the forceps along the full length of its blades; the divided vessels will be plainly seen on the cut surface, where they can be readily grasped with an artery-clamp, the peritoneum stripped back, and a ligature applied. Then, on removal of the first pair of forceps, the peritoneum retracts to its original position, the vessels lie free in their bed of connective tissue, and the ligature is subjected to no other strain than if it had been placed upon an artery in continuity; traction upon the parietal peritoneum by any shifting of the viscera or change in the attitude of the patient leaves it unaffected thereby.

This can be done wherever a clamp can be placed between the abdominal wall and the part that is to be removed, and the cases in which *ligature en masse* will be preferable appear to me to be only those in which the abdominal incision is so small or the anterior wall so thick and so slightly depressible that a clamp cannot be securely applied and the cut surface readily inspected and handled. The cut edges of the peritoneum can afterward be brought together with a continuous suture, if it is thought best to close this gap. The principle which, in my judgment, should govern the method of securing vessels divided in the removal of a viscus or a tumor from the abdominal parietes may be formulated as follows: The ligature should be applied to the vessels alone, underneath the peritoneum, and should under no circumstances include a circular layer or sleeve of parietal peritoneum that has been forcibly drawn up to form a pedicle, and will have to be held by the ligature against a diverging lateral strain.

A special and very valuable application of the substitution of isolated ligature of the vessels for the *ligature en masse* is the preliminary ligature of the uterine arteries in continuity, in supra-cervical or total abdominal hysterectomy. I have employed it with complete success in five cases, the first two of which were reported to the New York Surgical Society, January 9, 1889, and published in the *New York Medical Journal*, March 9, 1889. Each artery is sought for at the side of the upper part of the cervix by palpation of the broad ligament between the finger and thumb; after its position has been thus ascertained, a small incision is made through the peritoneum along its course on the front or, preferably, the back of the broad ligament, the artery separated from the veins with a director, and a ligature passed by means of an aneurism needle. The ureter lies to the outer side and is easily avoided. When both uterine arteries have been thus tied, and the ovarian vessels secured, as above described, by clamps, both ovaries and tubes and the body of the uterus can be removed by a transverse incision just above the clamps and ligatures, and the cut surface will be almost absolutely bloodless. The cervix can then be removed by cutting through between it and the bladder into the vagina and then cutting around it with scissors, or, of course, the cervix can be removed without previously cutting away the body of the uterus by cutting through each broad ligament to the side of the uterus, carrying the incisions through the peritoneum on the front and back of the uterus, and then working down through these latter incisions to the vagina as in the other case. The hemorrhage from this part of the operation is trifling, and as the cut surface is freely exposed to view, any vessel that may require it can be readily caught and tied. The following record of a hitherto unpublished case (my fourth) may serve to show the details.

F. W., forty-eight years old, colored, unmarried, had suffered for a number of years from abdominal pain and discomfort, and profuse hemorrhages from the womb attributed to a slowly increasing abdominal tumor situated in the hypogastrium. When I first saw her, in March, 1889, she was greatly reduced in strength and had been confined to bed for several weeks. Examination showed a solid, irregular, movable tumor filling the space between the umbilicus and pubes, and extending a hand's breadth to either side of the median line. The cervix could not be reached *per vaginam*, and the upper wall of the vagina was somewhat depressed by a firm, rounded mass, movable and apparently continuous with that lying above the pubes. The diagnosis of multiple uterine fibroids was made, and an operation for their removal was proposed and accepted. I sent the patient to the New York Hospital, and operated there March 26, 1889.

The peritoneal cavity was opened by an incision extending from a little above the pubes to the umbilicus, and through this the tumor and both ovaries were with some little difficulty turned out. By division of some broad adhesions between the rectum and the back of the uterus, Douglas's pouch and the posterior surface of the broad ligaments were freely exposed to sight and touch. The two layers of each broad ligament were found to be widely separated from each other near the uterus by the development of a fibroid low down upon the back of this organ, and each uterine artery could be felt lying much nearer the anterior than the posterior layer. The left one was first sought for through an incision in the posterior layer low down in the pelvis close beside the above-mentioned fibroid; it was found at the depth of about an inch, raised upon an aneurism needle for inspection and identification, and tied with catgut. The search for the right uterine artery was more difficult, because of its even greater distance from the posterior layer, but it was ultimately secured and tied, although not so cleanly isolated as the other had been. Up to this time twenty-five minutes had been consumed in the operation, fully ten more than in any of the preceding operations, the delay being due partly to the difficulties created by the depth at which the arteries were placed, and partly to an intercurrent exploration made to ascertain if they could be exposed and recognized with certainty close to their origin upon the anterior branch of the internal iliac artery.

The outer portion of each broad ligament was then clamped with hæmostatic forceps well below the ovary, each ligament completely divided with the knife above the clamp, the cuts united by incisions through the peritoneum covering the front and back of the uterus, and through these incisions the uterus was peeled away from the peritoneum well down to the cervix, and then its body cut away by a transverse cut. There was no bleeding from the cut surface.

The stump of the uterus was seized with Volsella forceps and drawn upward and backward, the cut

edge of the peritoneum adjoining the bladder drawn forward, and the anterior surface of the cervix rapidly dissected out until the vagina was opened into, the dissection being guided by the left fore-finger introduced through the vulva into the vagina. After the opening had been made the finger was withdrawn and reintroduced into the vagina through the opening to serve as a guide in the division of the remaining attachments of the cervix; this was quickly and easily made with scissors, taking care to cut on the sides between the ligated uterine arteries and the cervix. There was no hemorrhage requiring attention, except from two small vessels divided in the dissection of the anterior surface of the cervix.

Turning then to the cut surfaces of each broad ligament at its outer part, where held by the clamp, the bunch of divided vessels was caught with another clamp, drawn out of its peritoneal sheath, and tied with catgut. The removal had thus been made and all bleeding arrested or prevented by six catgut ligatures, two on the uterine arteries, two on the bunches of ovarian vessels, and two on small bleeding points between the bladder and vagina.

The remaining details may be briefly given. The peritoneal flaps raised from the front and back of the uterus were turned down toward the vagina so that their serous surfaces were opposed to each other, and the sides of the peritoneal gap left by division of each broad ligament were brought together by a continuous catgut suture; a rubber drainage tube was placed in the vagina so that its inner end projected about two inches into the peritoneal cavity, and the anterior incision was closed. The vagina was loosely packed with iodoform gauze. The drainage tube was removed after forty-eight hours; loose packing was kept in the vagina for a week, and this passage was occasionally cleaned with a douche. The patient made a good recovery.

The capital point to be attended to is that the uterine arteries should be tied sufficiently low down in the pelvis, before branches of any considerable size are given off, for otherwise time will be lost in securing these branches when they are subsequently divided. In case of accident, such as the slipping of the knot of the ligature, or the wounding of the artery or of a branch by the aneurism needle, or of hemorrhage from an unsecured branch, the bleeding can be easily arrested by pressure with the finger upon the corresponding internal iliac artery or its anterior branch, and an opportunity thus afforded leisurely to repair the damage or secure the wounded vessel.

The advantages of the method are apparent: rapidity and ease of execution, absolute and permanent security against hemorrhage, relief from the necessity of creating strangulated stumps with the concomitant risks of setting up suppurative or septic processes, and immediate closure of the abdominal wound. In cases in which it may be deemed desirable to retain the cervix, it can be entirely shut off from the peritoneal cavity by drawing the peritoneum together over it, and its raw surface and that of the subperitoneal space can be drained by a tube placed in the cervical canal and brought out through the vagina. If the operation is undertaken for procidentia, the cervix may be retained and fixed in the lower angle of the abdominal wound, as in one of my fibroid cases, or it may be removed and the upper cut edges of the vagina fixed in the same place, as was recently done with success by my friend and colleague Dr. William M. Polk.

Whether or not the isolated ligature of vessels upon the cut surfaces of the base of implantation of broadly pedunculated tumors of the ovary and of those formed by distention of the tubes can be advantageously substituted for the *ligature en masse* I have not yet had an opportunity to determine by trial, but I believe that it can be. Certainly the ovarian artery can be thus secured, and it does not seem probable that the branches coming from the side of the uterus will prove too large or too numerous thus to be safely and promptly secured. It is within the experience of all that a heavy silk ligature drawn with all the force that it will bear about such a pedicle does not always prevent bleeding, but that separate ligatures need in addition to be placed upon one or two spirting vessels. The trial can be easily made, and, I believe, without serious risk.

A CASE OF TUBAL PREGNANCY TERMINATING SPONTANEOUSLY PER VAGINAM.

By P. C. WILLIAMS, M.D.,
of Baltimore.

January 29, 1889, I was called to see Mrs. B., whom I had attended in 1888 for a severe vaginismus, which was greatly relieved when I left Baltimore in September, 1888. I found Mrs. B. much improved in appearance since I had seen her in September. She had gained much in strength, had an excellent color, and was able to exercise with more comfort than she had done for many months. I was surprised when she told me that she thought she was pregnant, and she desired me to ascertain whether it was true.

Upon inquiry she informed me that she had menstruated freely about the *middle of October*—had not menstruated in November or December—but during that time had decided leucorrhœal discharge which was frequently colored either *red or brown*. At the time of my visit (Jan. 29th) her strength and appetite were good, her figure plump and full, and her color excellent. There was also increased fulness of the mammary glands—but there was no "morning sickness," no nausea at any time.

External examination revealed nothing special, except enlargement of abdomen and *tenderness over the pubic region.*

Examination with speculum revealed vagina and labia of natural color, the cervix uteri normal in size, but rather *soft* to the touch; the *os uteri patulous* and emitting a free mucous discharge. Under these circumstances I felt satisfied that she was not pregnant and so expressed myself to her.

She still insisted that she was pregnant, and wished me to explain her failure to menstruate during the past two months, and her increased fulness of abdomen and breasts. This I was unable to do.

During the month of February I kept her under observation. During that time there was a gradual and steady increase of more or less bloody mucus, accompanied with pain of considerable severity, which *she* always located "in the region of the bladder."

During the latter part of February I found increased fulness and hardness over the pubic region, extending toward the left side, and I then thought that I could detect the outline of a fœtus. Further investigation proved this to be true.

After careful external examination I inserted two fingers of my left hand into the anterior "cul-de-sac," and then by steady pressure upon the abdomen with my right hand I could distinctly feel a tumor descend upon them, and I could readily produce abdominal ballottement. By cautious pressure with my hands—one in the vagina and the other on the abdomen—I could distinguish the outlines of the body and limbs of the fœtus. Being thus satisfied that she was pregnant; and also feeling convinced that the fœtus could not be *in utero*, I determined to settle that question. Accordingly I inserted a vaginal suppository about *two inches long*—which I had been using to allay the pain—into the cavity of the uterus. It entered the *os* with great facility, and this induced me to introduce my finger *in utero;* which proved beyond all doubt that the uterus contained no fœtus. This convinced me that it was a case of *extra-uterine pregnancy*.

Furthermore, the constant increase of bloody discharge from the vagina led me to suppose that I had to deal with a case of *tubal* pregnancy—with the fœtus just outside the *left horn* of the uterus. This bloody discharge continued with more or less abundance during the month of March, and about the 20th of the month the pain became more and more severe, and it required large doses of opium to restrain it within the limits of endurance.

At this juncture, viz., early in March, I communicated my opinion to Prof. Howard, and I told him that I would probably have to call upon him to relieve my patient by a laparotomy. Being anxious to save my patient the burden of thinking over the impending operation, I determined not to inform her family of her grave condition until circumstances would demand active intervention. Finding, however, that my reticence subjected me to very severe criticism from her friends outside of her family, I concluded that I ought to explain the situation to her husband.

This I did fully on the evening of March 30th. Early the next morning, April 1st, her husband came for me, and said that his wife had suffered intensely all night, and that the anodynes could not control the pain. I went with him immediately, thinking that the time for the laparotomy had come.

When I reached the house I found her suffering great agony. I at once put her under chloroform, and proceeded to examine per vaginam. I introduced my finger *in utero* and to my great surprise and unutterable relief I discovered that the *fœtus had descended into the uterus*, and that my patient *was in labor*. After three hours she expelled a fœtus about *four months old*, which gave feeble evidences of life and then expired. The placenta was extracted by gentle traction upon the cord. This was followed by slight hemorrhage, which gradually diminished under the use of ergot until it assumed the quantity and quality of ordinary lochial discharge.

For some days there remained an area of induration, about half the size of my hand, in the left iliac region. This induration gradually decreased in area, until to-day (May 10th) there is a hardness resembling a tumor about the size of an English walnut, a little to the left of the median line, and about half-way between the umbilicus and the pubis. With this exception my patient has returned to her normal condition, and I hope will soon be able to resume her household duties.

Thus has terminated favorably a case unique in my experience; and one that caused me grave anxiety for many weeks.

MEDICAL PROGRESS.

A new Symptom of Pericarditis.—In some cases the diagnosis of effusion into the pericardium is difficult; and a symptom, first noted by Bamberger, is said to be constantly present, and to aid materially in arriving at a correct conclusion. Puis, in the *Wiener medicinische Wochenschrift* (quoted in the *British Med. Journ.*, July 6, 1889), early in this year, has again attracted attention to the point. By percussion of the patient in a sitting position, or when lying on the right side, there is a muffled tympanitic resonance or diminished resonance over the left side of the thorax behind, extending downward from the angle of the scapula; and at the place of greatest loss of resonance there is distinct bronchial breathing and bronchophony, with increased vocal fremitus. If the patient is made to bend forward, a portion of the dulness completely disappears, another portion becomes tympanitic, and no bronchial breathing is heard. This change is more marked still if the patient assumes the knee-elbow position. The physical signs observed are ascribed to compression of the lower lobe of the left lung by the fluid in the pericardium, and is found chiefly in young adults with chests which are elongated or nar-

rowed antero-posteriorly. The presence of pneumonia or pleuritis is contra-indicated by the alteration of the physical signs when the position of the patient is changed.

Salve for Pityriasis Versicolor.—The following salve, which is recommended by the *Deutsche medicinische Wochenschrift*, June 6, 1889, as an efficient remedy in cases of pityriasis versicolor, should be rubbed into the affected skin every evening and washed off with soap and water the following morning:

℞.—Salicylic acid . . . 3 parts.
Precipitated sulphur . . 10 "
Vaselin } . . . āā 50 " —M.
Lanolin }

Cholecystotomy.—MR. LAWSON TAIT states that he has now performed fifty-four cholecystotomies, with two deaths, which were not in the least degree attributable to the operation, but simply to the progress of the disease; we may take it, therefore, that the true mortality of cholecystotomy is not more at present than four per cent. Of the cases operated upon so far there has been not a single case of recurrence of the disease, so that this argument which is put forward in favor of cholecystectomy has no foundation whatever. As a matter of fact, gall-stone is not a disease of the gall-bladder, for it is perfectly evident that the stones are not formed there, although it is true that there they grow; just as we know that in the great bulk of cases stone in the bladder is not a disease of the bladder originally, for the stones are in most instances formed in the kidney. Biliary fistula after cholecystotomy can only be permanent when the operation happens to have been performed at a time when a gall-stone was impacted in the common duct—at least that is his experience; and he can hardly imagine any other condition than obstruction of the common duct making this condition permanent. In three of his cases he crushed this obstructing gall-stone, and succeeded in getting a free road through the common duct. In one case he did not succeed; the patient, after living some years with a biliary fistula, died of phthisis, though he believed that the phthisis was a condition perfectly independent of the biliary fistula. On post-mortem examination there was found a series of gall-stones obstructing the common duct, only one of which he had succeeded in breaking up. It must be evident to the least skilled observer that in these cases removal of the gall-bladder would have been the most foolish of all possible proceedings, for the bile must have regurgitated immediately into the peritoneum. The cases in which the biliary fistula was alleged to remain permanently really constitute the strongest of all arguments against the operation of cholecystectomy, and of this operation he says that it is one which can be performed with greatest ease when there is no need for it—that is to say, when the gall-bladder is free from adhesions and perfectly healthy; but in those conditions where it might really be found advantageous—that is, where the gall-bladder is in a condition of chronic suppuration and greatly thickened by disease—the operation would be an absolute impossibility in the living body. Therefore, before we can judge as to its mortality, we must know not only how many cases have been performed, and what the mortality of these is, but we must know how many times it has been begun and left unfinished, and he ventures to say that the list will be found to be an immensely heavy one.—*Lancet*, June 29, 1889.

Chlorotic Dysmenorrhœa.—DR. MONIN, in the *Revue de Thér. méd.-Chir.*, June 1, 1889, advocates the following treatment in cases of chlorotic dysmenorrhœa:

℞.—Spirits of balm }
Tincture of saffron } . . āā f℥jv. —M.
Tincture of iodine }

Sig. Twelve drops after each meal, to be continued for two months. Every week a hot bath should be given, to which should be added about four and one-half ounces of chloride of ammonium.

The Heredity of Myopia.—If the opinions of various ophthalmologists concerning the heredity of myopia were recorded here, the result would be an accumulation of vastly conflicting statements. This, however, would be largely due to lack of precision in investigating the subject. Lately DR. MOTAIS, in *L'Abeille Médicale* of June 17th, has carefully studied both the history and course of disease in 330 cases of myopia occurring in young people, and has arrived at the following conclusions:

1. The hereditary influence of myopia is manifest.

2. Out of 330 cases the families of 219 were afflicted with the same disease. This shows a percentage of 65 per cent.

3. Hereditary myopia is distinguished from acquired myopia by

a. Its more early appearance.

b. Its more rapid development.

c. Its greater severity.

d. Its being more frequently followed by other completions.

In short, hereditary myopia is far more serious than the acquired form of the disease.

4. Myopia is usually transmitted from the father to the daughter (86 per cent.) and from the mother to the son (79 per cent.).

5. The principal conditions which favor the transmission of hereditary myopia are:

a. Use of the eyesight under bad hygienic surroundings, whether in school or at home.

b. Astigmatism, 14 per cent.

c. Microsæmia (diminution of the orbital arch), 16 per cent.

6. The increase of the disease in hereditary cases was, in 6 per cent. of the cases, found to be mainly the fault of those who had charge of the child's education. If care is not taken, acquired myopia will not restrict itself to the individual but may also be transmitted unto their children.

Suprapubic Lithotomy in Young Children.—DR. ALFRED LENDON, Lecturer on Forensic Medicine, University of Adelaide, has operated for vesical calculus in male children under five years of age, three times within twelve months, and with complete success. In each case the rectum was distended with the bulb of a spray-producer as a substitute for Petersen's bag, and the bladder washed out and then distended with boracic acid lotion. The skin-incision in no case exceeded one inch and a half. The bladder was not sutured; the skin wound was

brought together with horsehair, and a drainage-tube inserted which projected into the bladder. The first patient was four years of age; the calculus weighed fifty-eight grains; urine passed through the urethra on the eleventh day, and ceased to pass through the wound on the thirteenth. The second patient was not quite two years old; the stone weighed one hundred grains; urine passed naturally at the end of the first week, ceasing next day to pass through the wound. In the third case the patient was three and a half years old; the calculus weighed forty-five grains; the urine passed through the urethra on the seventh day, and ceased to pass through the wound on the nineteenth. The drainage-tube was removed on the day of the operation in the second and youngest case, on the second day in the first, and on the third day in the third case. Dr. Lendon, who writes his experience in the *Australasian Medical Gazette*, states that, had the proper instruments been available, he would have performed litholapaxy in preference to lithotomy. For a surgeon who had no special experience of vesical surgery, suprapubic appeared in many respects preferable to perineal lithotomy. In Dr. Lendon's case the chief difficulty was the extraction of the stone after the opening of the bladder.—*The British Med. Journal*, July 6, 1889.

Chapped Hands.—The *Revue de Thèr. méd.-Chir.*, June 1, 1889, gives the following salve, which, it says, is a most valuable toilet article. It keeps the hands white and smooth, and quickly remedies all redness and roughness of the skin:

Lanolin.	℥iijss
Liquid paraffin	℥ijss.
Vaniline	grs. ij.
Attar of roses	gt. j.—M.

The salve should be applied morning and evening.

Inoculation of Tuberculosis through Vaccination.—DR. E. PIPER, in the *Centralbl. für klin. Med.*, June 8, 1889, states that the danger of being inoculated with tuberculosis through vaccination is very slight. As far as human lymph is concerned, practitioners universally abstain from using that of tuberculous, scrofulous, or rachitical subjects. Again, the danger incurred from using vaccine taken from tuberculous animals is very slight, as the virus is usually obtained from very young animals, in which the disease seldom, if ever, occurs.

Dr. Piper, after vaccinating thirty-eight consumptives, subjected the lymph obtained from them to a most careful examination, but failed to find any tubercle bacilli. He further asserts that even in case the bacilli were inoculated during vaccination, that the disease would merely be a local one, and in substantiation of this theory mentions the local tubercles which are frequently found on the hands of those having dissected tuberculous subjects.

Injections of Lemon-juice in Severe Epistaxis.—The *Centralb. für klin. Med.* of June 15th, says that DR. FAUCHON, of Orléans, France, obtained immediate relief in a severe case of epistaxis by the injection of the juice of a freshly squeezed lemon. So far he has only had the one occasion to use the remedy.

A Formula for Aphthous Stomatitis.—

℞.—Salicylate of soda . . .	20 parts.
Distilled water . . .	100 "

Dissolve.

In cases of aphthous stomatitis the inflamed parts should be painted with the above solution five or six times during the day, particularly after meals. The mouth should previously be well rinsed out with tepid water.—*L'Union Médicale*, June 15, 1889.

Differences of Temperature of the Two Sides of the Body a Symptom of Cerebral Lesions.—At the meeting of the Neurological Society of London, which was held May 10th, PROFESSOR HORSLEY read a paper on clinical observations during the past seven years on the value of differences observed in the temperature of the two sides of the body as symptomatic of cerebral lesions. The lecturer desired to draw attention to the practical importance of the subject. He stated that an analysis of eighteen cases observed by him had proved that notable asymmetry of the two sides of the body occurred when a lesion was situated in what he wished temporarily to call the corpus striatum frontal plane of the hemisphere, this on the surface of the cortex passing through the ascending frontal gyrus. Further, that, as a rule, the converse also was true—namely, the occurrence of a lesion in other parts of the hemisphere was not accompanied by change in the temperature of the opposite side of the body. When, as in the former condition, change did occur, it was, with very rare exceptions, evidenced by a rise of temperature of the opposite side of the body. The solution of the problem could only be determined by experiment, and, until that was done, he deprecated the use of such expressions as "heat centres," etc., the existence of the difference, although a very valuable fact, being only so far ascertained. The discussion was continued by Dr. Hughlings Jackson, Dr. Bastian, Professor Schäfer, Dr. Beevor, and Dr. Mickle. There was a general agreement on the facts of the case, and their practical and scientific importance; but it was felt that much clinical and experimental work must yet be done before certainty of interpretation could be reached.—*British Medical Journal*, June 22, 1889.

Pylorectomy.—We learn from the *British Medical Journal* of July 6th, that on June 26th SIR WILLIAM STOKES performed the operation of pylorectomy in the Meath Hospital on a female patient, aged forty-eight, suffering from cancer of the pylorus. This is said to be the third case in which this formidable procedure has been adopted in the United Kingdom, Mr. Southam's and Mr. McArdle's cases having been the first and second. The operation, in Sir William Stokes's case, lasted over two hours. The patient subsequently rallied fairly well, and continued to progress satisfactorily up to 9.30 P. M. We regret to learn that she then became alarmingly weak, and notwithstanding the efforts that were made to revive her, the weakness continued to increase, and at 11 P. M. she became collapsed, and died at 11.35 P. M., just twelve hours after the operation. The statistics of the operation so far are not encouraging, for of seventeen cases operated on for pyloric disease, there are said to have been only four recoveries.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.
SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

SATURDAY, JULY 27, 1889.

THE MORTALITY OF PNEUMONIA.

WHETHER the mortality of acute pneumonia has changed during the past decades is a question of some importance, and since the appearance of Dr. Hartshorne's paper last year (THE MEDICAL NEWS, April 7, 1888, p. 373), in which he claimed that there was very striking increase, due in part, at least, to change of treatment, a widespread interest has been aroused in the matter. Statistics have been published which could be handled so as to favor either side, and it became evident that we needed a thorough and careful sifting of the figures of one of our large institutions with records available for the past fifty or sixty years. This want has been supplied by the admirable paper of DRS. TOWNSEND and COOLIDGE, in our present issue, who have analyzed with a scrupulous care and painstaking labor in the highest degree creditable, the thousand cases which have been treated at the Massachusetts General Hospital from 1822 until the present day.

The first evident fact in their tables is that a proportionally larger number of cases of pneumonia have been admitted during the last decades, the result doubtless of an increase in the class of citizens which looks to charity for relief in time of sickness.

As to the mortality itself, there has been an almost unbroken rise from 10 per cent. in the 1820 decade to 28 per cent. in the present one, and should the authors' labors have ceased here, their figures would have told heavily in favor of the great increase of the death-rate. There are, however, important modifying influences which must be considered. In Chart IV. the important influence of age upon the mortality is shown, a rapid increase occurring after the thirtieth year. The records show that a proportionately greater number of patients over fifty have been admitted in the later decades, the average age having increased from twenty-five and a half years in the twenties to thirty-four and a half in the eighties. A study of the complications, and of the previous condition of the patient, whether delicate, or whether addicted to alcohol, is given in Chart VI., which indicates that the ratio of such cases has greatly increased, rising from about 10 per cent. in the thirties to over 25 in the sixties. The race factor as an influence has become extremely important, particularly in our large city hospitals, in which the Italians and Huns are now so common. Among the native Americans the percentage of all the fatal cases is lower than in the Irish or other foreigners, and excluding the complicated cases, the percentage is still more striking: Americans, 9 per cent.; Irish, 11 per cent.; and other foreigners, 14 per cent. In the earlier decades the relative proportion of American patients was very much greater, as shown in Chart VII.

In short, the accurate sifting of the figures, and a study of the history of individual cases, bring out clearly that three important factors have influenced the mortality, viz.: a steady increase of the average age; an increase in the number of intemperate and of delicate patients, and of the complicated cases; and a great increase in the proportion of the foreign-born. Chart X., which represents the mortality in decades, excluding all cases which died over fifty years of age, or which were intemperate or delicate, or with serious complications, shows extremely little variation throughout the entire period of seventy years, and the authors conclude that at the Massachusetts General Hospital the mortality of acute lobar pneumonia has remained practically the same from 1822 to 1889.

An interesting analysis is also given of the change in treatment. Chart XI., showing the period of treatment in the heroic, transitional, and expectant stages, would seem to indicate that this rise of mortality in the total number of cases took place during the period prior to 1860.

It is interesting to note that the stay in hospital has varied very little in the different decades from a period of three weeks and four days.

The authors are to be congratulated upon this excellent piece of work, which will be duly appreciated by the profession, all the more as it comes from the "Massachusetts General," the hospital of Jacob Bigelow and of Jackson, of Channing and of Ware, of Shattuck (Sr.) and of H. I. Bowditch—men who have adorned our calling, and whose patient labor in the past made the present contribution possible.

THE SANITARY ADMINISTRATION OF DAIRY FARMS.

MILK inspection, as usually practised, has for its object the detection, by chemical analysis, of impurity and adulteration, and is, therefore, of great economic and hygienic advantage. The tests are made of samples procured at various points of distribution, but the investigation rarely extends to the source of the supply. By thus limiting the inquiry to the condition of the supply as furnished for distribution, a not uncommon and most important source of contamination is left entirely unguarded, and may not even be suspected until an outbreak of disease leads to an investigation of its cause.

The evidence is not wanting to show that cows' milk may serve as the disseminator of infectious disease among human beings. Typhoid fever, scarlatina, and diphtheria have all been disseminated in this way. It is now generally admitted that tuberculosis may be conveyed through the medium of cows' milk. Unfortunately, chemical analysis is of no avail in detecting the subtle infections which communicate these disorders, and hence the tests usually applied afford no protection against a possible source of virulent disease. There is evidently pressing need of enlarging the scope of inspection by making it include a rigid inquiry into the sanitary administration of the dairy farms themselves. *The Practitioner* for January, 1889, contains an article on the last-mentioned subject by DR. SHIRLEY F. MURPHY, which exposes the deficiencies of the ordinary methods of inspection, and shows how they may be remedied.

The health of the cow in its relations to the health of the drinkers of her milk, and the protection of milk from unhealthy surroundings and against infection or contamination, are subjects which have received more consideration in England than in this country. The English Contagious Diseases (Animals) Act of 1878 gave to the Privy Council power to issue general or special orders for the registration by the local authority of all persons carrying on the trade of cowkeepers, dairymen, or purveyors of milk, for the inspection of cattle in dairies, for prescribing and regulating the lighting, ventilation, cleansing, drainage, and water-supply of dairies and cowsheds, for securing the cleanliness of milk-stores and milk-shops, and of milk vessels used for containing milk for sale; and, lastly, for prescribing precautions to be taken for protecting milk against infection or contamination. This Act was further supplemented by the Acts of 1885 and 1886, which extended the authority already conferred. The legislation is, however, faulty in an important particular, inasmuch as it takes no cognizance of the circumstances under which the cow is placed in the meadows. It is very essential to the health and good condition of the cow and of those who drink her milk, that the drinking-water should be free from excremental and other pollutions. This fact seems to have been entirely lost sight of.

With its defects, however, the English law is far superior to any legislation that we in this country have upon this subject. In fact, sanitary legislation applicable to the cow in her shed and to all the circumstances of her life, her individual cleanliness and health, and the diseases which are known to have an effect upon her milk, is only beginning to attract attention. The sanitary regulation and the improvement in the condition of dairy farms have been due to the desire of dairymen to meet the requirements of modern knowledge rather than to the necessity of complying with statutory obligations. Injury to business incident to outbreaks of disease through the sale of impure milk has also been an incentive to vendors of milk to insist upon the regulation of dairy farms in a manner to prevent such calamities.

Milk being so universal a beverage, and the facility with which it may be the carrier of infection, imparted to it mainly at the farm, being recognized, the systematic inspection of dairy farms under adequate regulations is imperatively demanded in the interests of the public health. These regulations should be broad in their application, and made uniform for an entire State. It is commonly the case that milk produced in one county is distributed entirely beyond its limits, and hence local laws may be inoperative against the source of the evil.

Milk infection may be the effect of human agency; at least, it is safe to adopt this theory until disproved. It is also believed that the cow herself can suffer from some malady which may give rise to it. The

precautions prescribed by the law should be taken for the exclusion of both possibilities. The health of the cow should be maintained by the strictest attention to her hygienic surroundings. Pure water for the cow to drink, and for washing the pails and cans, is most essential. The cleanliness, ventilation, and drainage of the sheds are also matters of great importance. The milk should be guarded against contamination in handling and in storage. Persons suffering from dangerous infectious diseases should be prohibited from milking cows, handling milk vessels, and from taking any part in the business. Cases of infectious diseases arising in a herd should be isolated at once. The habit in Denmark of washing the hands after the milking of every two cows, is a useful precaution against the communication of dangerous udder disease. Udder disease undoubtedly impairs the wholesome quality of the milk. Infantile diarrhœa has not infrequently been traced to this disorder. When tuberculosis affects the udder, there is danger of transmitting the disease to the consumers of the milk. The prevalence of tuberculosis in cattle whose flesh is used for food, and the proof of the infectiousness of the milk of tuberculous cows, furnish sufficient reason for rigid inspection and for precautions, not only in the use of the milk, but also of the flesh of animals thus diseased.

The quarantining of infected animals and the withholding of their milk from the market, should also include the prohibition of the removal of any animal of such a herd, as a means of restricting the spread of the disease. Regulations for the sanitary administration of dairy farms are for the benefit of the dairyman as well as the consumer of milk. If judiciously administered they need not work any injury, for, as Dr. Murphy remarks, "they are to be used more for the purposes of education than for prosecutions, and the latter is reserved for cases of flagrant disobedience." In the absence of such regulations there is no certain knowledge of the quality of the milk distributed, and the supply must therefore be regarded with suspicion. The consumer, however, can protect himself by boiling the milk, a plan which is now generally recommended, and which should be adopted when there is real danger of infection, and, in fact, whenever there is no definite knowledge of the source and quality of the milk.

As will be seen by a notice in our News Item column the annual meeting of the State Medical Society of Pennsylvania has been further postponed until June of next year. In view of the decided indications of the improbability of being able to obtain a successful meeting in September, and of other concomitant reasons, the Committee of Arrangements has acted wisely in assuming the authority and deferring the meeting until next year.

THE profession of Chicago will not long be without a great medical library. A nucleus of three thousand volumes has been secured by the purchase of the collection of the late Dr. J. S. Jewell; a few medical men uniting, on very short notice, to save it from dispersion under the auctioneer's hammer. The *Journal of the American Medical Association* intimates that a temporary lodgement of this choice collection will be found with the Chicago Public Library until a suitable centrally located building can be procured.

DR. JOHN B. ROBERTS has been elected Professor of Surgery in the Woman's Medical College of Philadelphia, to succeed Dr. W. W. Keen, resigned.

DR. CHARLES B. NANCREDE, of Philadelphia, has just been elected Professor of Surgery in the University of Michigan, Ann Arbor.

DR. JOHN A. CONNER, who was graduated at the University of Pennsylvania, Class of 1867, and who is the Medical Officer of the United States Commission to the International Exhibition in Paris, has been authorized by the French Government to practise his profession in France with his American diploma, not having passed his French medical examination. He is the third American who has been officially allowed to practise medicine in France without a French diploma, Dr. Marion Sims, of New York, having been the first one.

THE *Breslauer ärztliche Zeitschrift* came to an untimely end on June 29th, it having been found impossible to secure the services of an editor of a "commanding personality" to supply the place of the late Professor Gscheidlen, who founded the journal and gave to it the high position it held in German medical literature during the ten years of its existence.

THE School of Medicine in Mexico comprises eighteen professors, and the curriculum lasts five years. Most of the text-books in use are translations of French standard works.

SOCIETY PROCEEDINGS.

AMERICAN OTOLOGICAL SOCIETY.

Twenty-second Annual Meeting, held at New London, Conn., July 16, 1889.

The Society was called to order by THE PRESIDENT, DR. J. S. PROUT, of Brooklyn.

DR. B. ALEXANDER RANDALL, of Philadelphia, read a paper on

INFLAMMATION OF THE TYMPANIC ATTIC AND PERFORATION IN SHRAPNELL'S MEMBRANE.

He reported twenty cases, fifteen of which had been seen in the past six months, and urged that the condition was not a rarity. It often coexists with one or more perforations of the other parts of the drum-head. If sought and recognized early, it is a less tedious and serious matter than these attic inflammations are generally considered to be. He cited some 120 cases reported by several observers among 10,000 patients, and while he had seen a still larger proportion, accepted this as the average. Passing over the treatment as having been already thoroughly discussed, he turned to the question of causation, and cited the views of Walb that infection from without through the "foramen Rivinii" was the starting-point. Contesting the view that any colotomatous opening in the flaccid membrane was wholly negatived by modern embryologists, he urged that the individual variations in the septa in the attic predisposed some cases to localized inflammations and led to perforation at this point; and that these cases, neglected or recurrent, formed the group from which the usual obstinate cases were derived. He, therefore, advocated scrupulous search in all cases for disease in this locality as promising to nip in the bud what might later become a disease notoriously difficult to control.

DR. S. O. RICHEY, of Washington, did not think that perforations of Shrapnell's membrane are so common as had been stated. His experience with the absence of perforation corresponds with that of others. He had had cases in which perforations in other parts of the drum healed, but the perforation in Shrapnell's membrane persisted. In treating these cases, besides using measures through the external auditory meatus, he had employed injections through the catheter consisting of nitrate of silver, 1 part; boric acid, 10 parts; glycerine, 20 parts; and water, 500 parts.

DR. GORHAM BACON, of New York, had not observed this condition so frequently as Dr. Randall. It is often difficult to see these perforations. In treating he had generally used Blake's extra-tympanic syringe. By persistent syringing and the use of astringents, cicatrization is often produced. These cases are, however, very tedious.

DR. J. A. ANDREWS, of New York, said that in treating these cases in which there is purulent inflammation of the attic with a large hole in Shrapnell's membrane, after injecting the cavity, he sucked out the fluid by means of an instrument consisting of a delicate metal tube with a curved extremity, to which is attached a rubber tube. He used a boric acid solution. After sucking out the fluid, he dried the cavity with cotton wrapped on a probe, and then blew in a fine cloud of boric acid.

DR. HERMAN KNAPP, of New York, said that there is a capital difference between perforations in the upper and those in the lower part of the drum membrane. Those in the lower part may close in a few days, while in the upper part they may continue for months or years. He thought this is due to difference in anatomical structure. The lower portion is a specific tissue with little association with periosteum, while the upper part is a duplicature of periosteum and skin. When the latter part is affected, the process extends to the periosteum leading to caries and necrosis of the bone.

DR. F. M. WILSON, of Bridgeport, Conn., reported

THREE DEATHS FOLLOWING SUPPURATIVE OTITIS, WITH TWO AUTOPSIES.

Cases in which death follows a first attack are so rare that it was thought of value to report these cases. The first patient was aged forty years, and for two weeks before coming under observation, had had pain in both ears. February 27, 1888, the pain in the left ear became very intense. March 1st, he became partially unconscious, and remained so with occasional convulsive movement until March 6th, when he died. The mastoid was drilled half an inch but no pus found. No autopsy was made.

The second case, a male, aged twenty-three years, was attacked with subacute otitis March 11th. Symptom of meningitis appeared with high temperature, and he died March 27th. At the autopsy one-third of the base of the cerebrum was involved in the purulent process, which extended up under the frontal convolutions. There was about half an ounce of turbid fluid between the dura mater and inner meninges. There was pus in the labyrinth and in the tympanic cavity.

The third case was that of a boy, aged ten years, who was attacked with suppurative otitis September 5th, and died about ten days later. At the autopsy the meninges were found normal, but an abscess containing two drachms of fluid was found in the cerebellum.

DR. WILSON also presented a mastoid drill provided with a guard which could be set at any desired point regulating the distance to which the drill entered. The edges of the drill are sharp, so that the opening can be enlarged horizontally to any desired extent.

DR. GORHAM BACON thought that in these cases, where we do not find any collection of pus in the mastoid cells, we are justified in investigating the condition of the brain.

DR. J. O. TANSLEY had had several of these cases, and has, without success, sought for some means by which we could differentiate between those in which there was meningitis and those in which there was abscess. In one case, Dr. Seguin made a diagnosis of abscess based upon conjugate deviation of the eyes. Subsequent autopsy showed the correctness of this diagnosis. In another case, the speaker suspected abscess, Dr. Weir opened the mastoid, but found no pus. He also exposed the cerebrum, and, two days later, the cerebellum, but found no pus. The patient died of suppurative meningitis.

DR. S. D. RISLEY showed that in the differential diagnosis attention to the temperature, in connection with symptoms of pressure, is of great importance. In meningitis the temperature from the outset will be higher than in abscess, and the symptoms of pressure come on later.

DR. J. A. ANDREWS, of New York, said that in the past year he had made a number of autopsies in cases of brain abscess. Brain abscess may continue for a considerable time without any very positive symptoms, but where there is meningitis or phlebitis, especially phlebitis, there is usually a sudden rise of temperature with chills.

DR. OREN D. POMEROY, of New York, related a case of brain abscess secondary to tympanic disease, in which the only marked symptom was a sudden rise of temperature, sometimes going up in half an hour from normal to 107°. Intelligence was unaffected until the last, the man gradually improved, but died suddenly. The autopsy showed a large abscess of the brain covering the petrous portion of the temporal bone.

DR. ARTHUR MATTHEWSON, of Brooklyn, said that it is often difficult to make a diagnosis between abscess and meningitis, and, in fact, many are mixed cases. In meningitis the pain is more marked than in abscess. In meningitis there is more likely to be optic neuritis, while in brain abscess he had noted a peculiar dark appearance about the retinal veins.

DR. SAMUEL THEOBALD, of Baltimore, thought that the treatment of the preliminary stage of these cases is important, and that a great deal might be done to prevent the occurrence of the conditions referred to. He had found benefit from local applications, especially atropine and cocaine, and morphine and cocaine. If the bowels were constipated, he should use a calomel cathartic. If there should be symptoms of cerebral implication, he should administer mercury in some form to secure its constitutional effect.

DR. E. FRIDENBERG, of New York, said that during the past eighteen months he had made autopsies on two patients who died from cerebral abscess. In one case suppuration had lasted a year, but there had been no symptoms until a week before death, except irritability of temper; there was some odor, but very slight discharge from the ear. A week before death the patient developed pain in the ear, slight tenderness over the mastoid, followed by fever and symptoms of brain pressure. A small abscess was found in the temporo-sphenoidal lobe. The roof of the tympanum was carious, and the meninges strongly adherent. In the second case the patient had had suppuration for years. Two months before death headache occurred, which was relieved by treatment. It recurred with fever; there was some pain on pressure over the mastoid process. The symptoms again disappeared under treatment. Three weeks later he returned with similar symptoms. The next morning vomiting occurred, and that evening he died. An abscess containing two ounces of pus was found in the temporo-sphenoidal lobe.

DR. T. Y. SUTPHEN, of Newark, thought that these cases of brain trouble almost invariably follow the arrest of the flow of pus. We should look upon them as instances of local trouble, and should treat the middle ear by fomentations, and, perhaps, by poultices to bring about free discharge of pus.

DR. R. A. REEVE, of Toronto, stated that in one case of death following acute suppurative otitis, there was the most profuse purulent discharge that he had ever seen, and it continued from beginning to end.

DR. B. ALEXANDER RANDALL referred to a case of cerebral abscess which occurred in his practice last year in a boy the subject of scrofulous disease of the elbow and other joints. He found both ears discharging, with caries of the auditory meatus on both sides. On the left all the mastoid tissues were involved. Under treatment the right side rapidly improved, and on the left side there was also improvement. The case was then transferred to his surgical colleague. Six weeks later the ears were still in good condition, but the patient was gradually failing from the constitutional trouble. An hour before death there was suddenly a discharge of at least two ounces of fetid pus from the ear. There was no meningitis, but a large abscess cavity was found in the sphenotemporal lobe, one-half inch from the tympanum, and connected with it by a sinus.

In cases where it is thought justifiable to perform exploratory trephining of the brain, an admirable and safe point is one and one-fourth inches behind, and an equal distance above the upper posterior margin of the osseous meatus. This avoids the major bloodvessels, and it would be possible to reach the cerebellum through it.

DR. E. E. HOLT, of Portland, Me., reported a case of

COMPLETE CLOSURE OF BOTH EXTERNAL AUDITORY CANALS BY BONE IN A PATIENT HAVING GOOD HEARING POWER, WITH A PREVIOUS HISTORY OF CHRONIC SUPPURATIVE OTITIS MEDIA.

T. M., aged eighteen years, was seen in April, 1889, for an affection of the eye. It was incidentally learned that he had had abscesses in both ears when seven years old, and the ears discharged more or less for six years, but stopped entirely five years since. Examination showed the canals of both ears of about half the usual length and occupied by a continuation of the skin of the meatus with no appearance of the membrana tympani. There was complete closure of the canal by what appeared to be bone by all the tests employed. The hearing power for the voice was good. The stop-watch was heard only when close to the ear; the tuning-fork was heard about ninety seconds both by bone and aërial conduction. König's rod of thirty thousand vibrations per second was heard by both ears. He heard less distinctly when both ears were closed by pressure on each tragus. Shutting the mouth and closing the nostrils did not seem to effect the hearing power much, if at all. Cases with closure of one meatus with the skin of the canal continuous over the obstruction have been observed, but the hearing power is very defective. Cases in which there is a small opening between the exostosis and the walls of the meatus are not uncommon.

DR. S. THEOBALD said that four or five years ago he reported a very similar case. The newly formed membrane was, however, nearer the orifice. The hearing power was good.

DR. HOLT also stated a case of

OTIIS MEDIA CATARRHALIS ACUTA,

accompanied with facial paralysis and impairment of accommodation of the eye of the affected side.

Judging from statistics, one would be led to believe that paralysis of the facial nerve in connection with acute catarrhal inflammation of the middle ear was not a common complication. In many cases the pain having been slight, and having passed off, and the paralysis having come on, the patient's attention is directed to this and he seeks advice for the latter affection, and the cause of the paralysis is recorded "a cold" or "rheumatic."

F. L., æt. twenty-four, seen May 19, 1889. Seven days before took cold, and right ear began to pain that night. This pain continued three days, when it subsided, and on the fourth day he was unable to use his lips properly. Examination showed all the characteristics of facial paralysis. Testing the eyes, there was found paralysis of accommodation of the right eye. This he knew to be a fact because he had previously had the patient under his care and recorded the test of his eyes; and also by the fact that since the improvement of the paralysis of the face the paralysis of accommodation had disappeared.

DR. S. O. RICHEY then read a paper on

THE PHYSIOLOGY OF THE INTRA-TYMPANIC MUSCLES,

which was the elaboration of a suggestion made by him at the Congress of American Physicians and Surgeons, in 1888.

EVENING SESSION.

DR. GORHAM BACON read a paper on

CYSTS OF THE AURICLE.

Of late a number of cases of so-called cysts of the auricle have been reported. Not one of them, however, seems to represent a genuine cystic tumor such as is found in other parts of the body. They all were situated on the anterior surface of the pinna and were of rapid development. They either were the results of traumatism and contained a sanguinolent fluid, or they developed without known cause. Mild inflammatory symptoms were present in all. The development within two or three weeks in almost all cases distinguishes them clearly from the slow and absolutely non-inflammatory development of true cystic tumors. All got well either by spontaneous absorption or by incision. He had seen at least half a dozen of these cyst-like sub-perichondrial swelling of the auricle. He considered them to be mild cases of perichondritis for these mild cases of circumscribed perichondritis may, instead of getting well, remain in this condition for a time and then develop into the full picture of a diffuse perichondritis. He reported such a case.

DR. KNOPP also described a case of genuine cyst of the auricle occurring in a girl nineteen years of age. The growth was double the size of a large filbert, distinctly cystic and had developed without known cause and without any inflammatory symptoms. The cyst was removed by operation, without rupture and was exhibited. These tumors are not frequent in the auricle, but they cannot be so rare as we might infer from otological literature.

DR. WILLIAM H. CARMALT, of New Haven, reported a case of

EPITHELIOMA OF THE MIDDLE EAR.

The patient a robust man, aged forty-seven years, was first seen in June, 1888, on account of a suppurating ear (left) which had existed forty-two years and had followed measles. The ear had given him no inconvenience with the exception of the discharge until a few weeks before he came under observation. He then began to have pain in and around the ear and the discharge was exceedingly offensive. The canal was blocked by a ragged but firm excrescence, very sensitive to touch. There was slight tenderness, but no swelling or pitting over the mastoid. The pain radiated through the side of the head and interfered with sleeping. At the second visit, the left side of the face was completely paralyzed. The case was regarded as one of epithelioma of the skin of the canal. The patient was seen by another gentleman, who thought the trouble might be a carious antrum. An attempt was, therefore, made to open the antrum, but the bone around it was so sclerosed that the cavity was practically obliterated. There was nothing of the nature of an abscess in the mastoid. The incision was then prolonged through the soft parts and into the external auditory canal. A mass of soft tissue was removed which proved to be carcinomatous and a drainage tube inserted. In the course of a few weeks the ear again became blocked up and the skin became involved. With the object of alleviating some of the distressing accompaniments of the condition, another attempt was made to clear it out. By chiselling away the bone posteriorly, free access to the ear cavity was obtained and the bone scraped apparently clean. No auditory apparatus was seen, simply a mass of carcinomatous tissue. The cavity was washed with a solution of resorcin and for a time the wound did well, but subsequently the disease reappeared. The discharge again became offensive and the patient exhausted and he finally bled to death without the condition being detected, probably from erosion of the lateral sinus. No autopsy was permitted.

EXECUTIVE SESSION.

THE ELECTION OF OFFICERS

for the ensuing year resulted as follows:

President.—Dr. Oren D. Pomeroy, of New York.

Vice-President.—Dr. Gorham Bacon, of New York.

Secretary and Treasurer.—Dr. J. J. B. Vermoyne, of New Bedford, Mass.

Members of Executive Committee of Congress of American Physicians and Surgeons.—Dr. W. H. Carmalt, of New Haven; alternate, Dr. F. B. Loring, Washington, D. C.

A committee consisting of Drs. S. C. Ayres and William W. Seely, was appointed to prepare a minute on the death of Honorary Member Dr. E. Williams, of Cincinnati.

The Society then adjourned.

AMERICAN OPHTHALMOLOGICAL SOCIETY.

Twenty-fifth Annual Meeting, held at New London, Conn., July 17 and 18, 1889.

WEDNESDAY, JULY 17TH.—MORNING SESSION.

The Society was called to order by the President, WILLIAM F. NORRIS, M.D., of Philadelphia.

DR. CHARLES S. BULL, of New York, presented

AN ANALYSIS OF NINETY CASES OF SIMPLE CHRONIC GLAUCOMA, WITH SPECIAL REFERENCE TO THE EFFECTS OF IRIDECTOMY UPON THE ACUITY OF VISION AND THE VISUAL FIELD,

and the following conclusions were formulated:

In endeavoring to draw some rational conclusions from the study of ninety cases, it seems wise to begin with a quotation from Priestley Smith, to whom ophthal-

mologists owe so much of their knowledge of the pathogeny and pathology of glaucoma.

1. In considering the expediency of an operation in chronic glaucoma, he says: "In every case of chronic glaucoma the responsibility of advising an operation is a heavy one, and should on no account be undertaken without a full explanation to the patient or his friends of the almost positive certainty of blindness on the one hand, and of the uncertainties which beset the operation on the other. Having regard to the age of the patient, the impossibility of great benefit and the possibility of a painful and accelerated progress, the prudent surgeon will only operate on the express desire of the patient to secure the only possible chance of benefit, however small it may be." Armed with the preceding precaution, it seems to be our duty to operate in cases of chronic progressive glaucoma, and the earlier the better.

2. If the disease in a given case seems to be stationary and is still in the primary stage, and if it be possible to test the vision and the visual field at short intevals, delay in operating is permissible; but a weak solution of eserine or pilocarpine should be used daily, merely as an aid in controlling the course of the disease. The examination of these patients should be at short intervals and should invariably include tests for visual acuity and the careful examination of the visual field.

3. If the disease exists in both eyes but with useful vision in both eyes, the eye in which the disease is the more advanced should be operated on without delay; and the surgeon will be guided in his treatment of the fellow eye by the result of the operation on the first eye.

4. To insure the best result, the incision should be made well in the sclerotic with a narrow cataract knife or a broad lance knife, and the entire iris, from one end of the incision to the other, should be carefully torn or excised from its insertion.

5. The most carefully performed iridectomy by skilful hands is sometimes followed by rapid loss of what sight still remains; sometimes partial, but, unfortunately sometimes total.

6. A successful result is in the majority of cases more likely to follow the operation if it is performed early in the course of the disease, but the maintenance of the existing degree of vision even in these cases is not invariable.

7. As regards the question of symmetry, it is probable that in the large majority of cases, probably as much as eighty per cent., the disease is sooner or later present in both eyes, and a careful study of the cases seems to establish the fact that there can be no specific interval of time which insures the second eye against an attack.

8. If the patient is old and feeble and one eye is still free from disease for a year or more after the other eye has become affected, it may be considered prudent to avoid an operation on the affected eye; as it is probable that the unaffected eye may remain free during the remainder of the patient's life.

9. The condition of the field of vision is no constant guide either in forming a prognosis as to the progress of the disease or in deciding as to the time of operation.

10. The acuity of vision bears no constant relation to either the success or failure of the operation.

11. The anterior chamber is usually shallow, is occasionally entirely absent, but is often apparently normal in depth. The condition of the chamber gives no reliable hint as to the state of the vision or of the visual field nor any indication as to prognosis.

12. The appearance and motility of the iris appear to have some bearing upon the prognosis, though perhaps not to the extent believed by Nettleship. The latter states that in the cases in which the iris reacts rapidly to eserine the operation proves successful. This has not always been the experience of the reporter, but in the majority of the cases in which eserine caused rapid contraction of the pupil, the visual acuity was fairly good and the field was not seriously limited.

13. The depth of the excavation in, and the color of, the optic disk seem to have no close connection with the defective vision or with the limitation of the visual field, nor did they offer any constant guide as to prognosis or to the effect of an operation upon the progress of the disease.

14. The condition of the intra-ocular tension is a very uncertain guide in deciding the time for operating. It may be normal or increased or even diminished. It does not even seem to bear any constant relation to the degree of visual acuity or to the state of the visual field. The steady maintenance of the increased tension, however, without any diminution, almost invariably indicates the necessity for an immediate operation, and this necessity is especially indicated if the tension is continually on the increase.

15. The health and age of the patient exert a decided influence upon the effect of the operation. Any marked evidence of senility is distinctly unfavorable to operation.

DR. H. KNAPP, of New York, said that during the past nineteen years he had operated on 670 cases of glaucoma, 226 of which were cases of chronic glaucoma. He thought that the prognosis may be a little more favorable than had been indicated by Dr. Bull. He had had four cases in which malignant disease followed operation for chronic glaucoma. He did not agree with the author as to the advisability of the continued use of pilocarpine or eserine in those chronic cases where operation seems doubtful. He advised its use when there are recurrent symptoms. In prognosis he was guided a great deal by the condition of the iris. His operations had been done with the lance-shaped knife. He considered it of great importance to reduce carefully the edges of the coloboma, not only by external pressure, but also by the use of the blunt probe. He was also careful not to make the operation too peripheral. Peripheral wounds are more liable to cystoid scars.

DR. EMIL GRUENING, of New York, then read a paper on

IRIDECTOMY IN GLAUCOMA.

He classified the different forms of glaucoma under the following heads: 1, acute inflammatory; 2, chronic inflammatory without visible degenerative changes in the iris; 3, chronic inflammatory glaucoma with visible degenerative changes in the iris; 4, simple glaucoma; 5, intermittent glaucoma; and described cases illustrative of these different varieties.

DR. S. O. RICHEY, of Washington, did not believe that simple chronic glaucoma was entirely a local affection. He thought that it is a local expression of a cause to be looked for in the nervous system. He had used eserine with satisfaction in the early stages, but supported

it by galvanism applied to the cervical ganglia. In some cases this will result in the avoidance of an operation.

Dr. Samuel Theobald, of Baltimore, had met with one case in which an attack of pronounced acute glaucoma was cut short by the use of eserine.

Dr. Bull thought that eserine is frequently used in too strong solution. A solution of half a grain to the ounce may cause iritis after a single instillation. He never uses a stronger solution than this, and often uses one as weak as one-tenth of a grain to the ounce.

Dr. B. Alex. Randall, of Philadelphia, confirmed the remarks in regard to the value of weak solutions. In one case of severe absolute glaucoma a solution of one-eighth of a grain to the ounce was entirely successful in relieving the pain. It has been used steadily for three years with no recurrence of the severe symptoms, and without the intervention of any inflammatory trouble.

Dr. S. D. Risley, of Philadelphia, said that in experimenting with weak solutions of eserine, he had found that a distinct effect was experienced from a solution as weak as one-thirtieth of a grain to the ounce. If this was applied three times a day, it would, in two days, cause distinct brow-ache. He had seen benefit from weak solutions where stronger solutions failed to give relief.

Dr. Henry D. Noyes, of New York, said that one point to which his attention was called many years ago was that in certain instances of evident glaucoma with a large amount of refractive error, it had seemed that the aggravation of the glaucomatous disease had been dependent upon the accommodative strain. In operating he had gradually withdrawn from the extremely peripheral place of incision. He preferred to come closer to the border of the cornea than some do. This involves less risk, and is easier of performance.

Dr. Theobald's experience tended to convince him that astigmatism is frequently the cause of glaucoma.

Dr. Arthur Mathewson, of Brooklyn, said that in one case of glaucoma in which iridectomy had been done without arresting the progress of the disease, a large injection of strychnine caused a decided improvement of vision, which continued. He had used it in other cases with good effect.

Dr. Emil Gruening then read a paper on

THE USE OF THE CURETTE IN ANTERIOR TRACHOMA.

After referring to the various measures proposed for the relief of this condition, he described an operation which he had employed in eleven eyes during the past two years. A six per cent. solution of cocaine was first instilled. The surface of the cornea and the vessels present were then scraped away with a gouge-shaped instrument, and the vessels followed well on to the conjunctiva. The eye was then washed with boric acid solution and warm compresses applied for four or five days. In three days new vessels formed and the operation was repeated. The ultimate result in all the cases was highly satisfactory. In old and protracted pannus this operation may be recommended for its directness, simplicity, and efficacy.

Dr S. D. St. John, of Hartford, had used this operation in one case with the highly gratifying result of increasing the vision from $\frac{4}{CC}$ to $\frac{16}{CC}$. This has since still further improved.

Dr. H. F. Hansell, of Philadelphia, read a paper on

CORNEAL ABSCESS,

describing its symptoms and referring to the differential diagnosis between it and ulcer. He protested against the use of cocaine in abscess or other inflammatory conditions of the cornea. A few drops of a strong solution will often destroy the epithelium. Instillation of eserine alternating with atropine was recommended. Operative interference should be limited to evacuation of the pus.

Dr. Charles J. Kipp, of Newark, then made some

FURTHER OBSERVATIONS ON MALARIAL KERATITIS.

He had called attention to this condition in a paper read before the Society, in 1880. He had seen one hundred and twenty cases of the disease. In all there had been paroxysms of malarial fever, and in ninety per cent. the corneal inflammation followed a few days after a paroxysm. In twenty-five per cent. the patients had suffered from similar trouble in previous attacks of malaria. The inflammation of the cornea occurred in the form of serpiginous ulceration, with narrow prolongations. The trouble began as a line of small grayish elevations, which soon broke down, forming a furrow of ulceration. In mild cases the duration is two or three days, while in severe cases it may last several months. There is a marked tendency to recurrence in subsequent attacks of malarial fever. In a few cases he had seen a similar affection in non-malarial individuals. The treatment consists in remedies directed to the general condition, and, in mild cases, with warm fomentations. In severe cases a one or two per cent. solution of nitrate of silver applied directly to the furrows after the use of cocaine answers well. In some very severe cases the actual cautery was employed. This arrested the progress of the disease and stopped the pain, provided the malarial trouble had previously been cured.

Dr. Noyes said that during the past fifteen or twenty years he had met with cases of superficial keratitis due to malaria. It is rare to find the deeper tissues invaded. He was led to suspect a malarial origin in cases in which there is exaggerated tenderness of the supraorbital nerve and distinct anæsthesia of the surface of the cornea. The form of ulcerative keratitis which has been described, he regarded as of mycotic origin, and had cured it by scraping thoroughly the lines of infiltration.

Dr. T. Y. Sutphen, of Newark, had seen cases similar to those described by Dr. Kipp in patients suffering with malaria, and in which there had been no distinct chill; the individuals have resided in malarious districts.

Dr. John Green, of St. Louis, had seen many cases in which malarial fever was followed by superficial keratitis, or keratitis modified by neglect or improper treatment. He had not met with the form described by Dr. Kipp.

Dr. Gruening had seen this form of ulcerative keratitis, but he had associated it with the teeth. These patients had tartar on the teeth, and had been in the habit of moistening the lids with saliva, he thought therefore that the source of infection was in the mouth.

Dr. Theobald had also seen for many years this keratitis associated with malarial trouble. These cases do not always show ulceration of the cornea. He had in a general way regarded this condition as analogous to

herpes zoster. He had once or twice seen iritis associated with the keratitis following malaria. In one case of malaria he had seen this keratitis with herpes zoster of the temple.

DR. J. A. LIPPINCOTT, of Pittsburg, read a paper on

IRRIGATION OF THE ANTERIOR CHAMBER.

This procedure is useful for the removal of débris in cataract extraction and of clotted or liquid blood. In order to accomplish this successfully it is necessary to have an apparatus which can be readily made and kept aseptic; which will always be ready for use; which can be easily handled and the movement controlled with one hand; whose ejecting force is capable of being easily regulated; and which is free from liability of forcing air-bubbles into the anterior chamber. As fulfilling these requirements he exhibited an apparatus consisting of a small metal receptacle with which was connected a rubber tube ending in a metal nozzle; the flow of liquid being controlled by a short piston in a rubber handle through which the rubber tube passed. The ejecting force can be varied by elevating or lowering the receptacle.

DR. GRUENING exhibited a small flask devised by von Graefe for the same purpose.

DR. HENRY D. NOYES then read a paper on

ENUCLEATION OF THE EYE IN PAN-OPHTHALMITIS.

There have been reported by various observers thirty or forty deaths following enucleation, almost all from meningitis. About one-half of the fatal cases have occurred after enucleation during acute suppurative pan-ophthalmitis. At the New York Eye and Ear Infirmary there have been no deaths from this cause, when no additional operation in the orbit, such as the removal of tumors, etc., has been done. The number of enucleations from 1868 to 1888 was 1164; the number of evisserations 17. Pan-ophthalmitis existed in fourteen per cent. of the cases. It seems fair to conclude that while a small risk to life is incurred by enucleation of the eye, the suppose increased risk by the existence of suppurative pan-ophthalmitis is not so far justified by the facts as to bar its performance in this condition.

(To be concluded.)

AMERICAN NEUROLOGICAL ASSOCIATION.

Fifteenth Annual Meeting, held at Long Branch, N. J., June 26 and 27, 1889.

(Concluded from page 83.)

JUNE 27TH.—AFTERNOON SESSION.

DR. J. H. LLOYD, of Philadelphia, read a paper entitled

A LATER HISTORY OF A CASE OF FOCAL EPILEPSY FOR WHICH TREPHINING AND EXCISION OF THE MOTOR CENTRES WERE PERFORMED.

Full details of the case had been recorded at the last annual meeting of the Association. At that time but three months had elapsed since the operation, and Dr. Ferrier, of London, had stated in a discussion that the time was too short for a decisive result as to the usefulness of the operation. Now that more than a year had passed further details could be given. Before the operation the patient had had many seizures daily. There was no fit for four months after the operation. Since that time, however, there had been some ten seizures in nine months.

DR. SPITZKA said there was a minority, but a powerful minority, of clinicians and physiologists who hesitated to accept the dictum that spasms were always of cortical origin when clonic in character and local in manifestation. There were well-authenticated cases of spasms, such as are generally described as cortical, which undoubtedly had their origin in the pons or medulla. He, therefore, thought it premature to advise surgical procedure when there was still doubt as to the position of the convulsive centre. He was of opinion that the seat of irritation in the great majority of cases of epilepsy was in the lower centres, such as Nothnagel's convulsive centre.

DR. MILLS mentioned the case of a man subject to unilateral convulsions beginning in the hand. There was a scar upon the head, and trephining was done at this spot in order to relieve severe pain probably due to trigeminal irritation in the scalp or dura. This operation relieved the pain, but caused the Jacksonian epilepsy upon the other side. The operation was repeated in the same spot, the membranes and cortex being removed to some extent, and with great success. It was an apparent illustration of the fact that convulsions may occasionally be the result of operations themselves.

DR. DERCUM had seen the same case and stated that the dura was not opened in the first operation. At the second trephination the membranes were found united. There was a pachymeningitis. The patient had surgical epilepsy. Six months elapsed between the operations.

DR. LLOYD said it was a question whether one could have localized epilepsy from irritation of lower centres, as Dr. Spitzka had intimated. He had always held the idea that such spasms were of cortical origin. In the case he had just described, the absence of fits for four months led him to believe that he had removed the parts concerned in their manifestation.

He had been hopeful of the efficacy of this method in the relief of such a disorder, and was not yet willing to give up the idea that something may be accomplished in this way. He thought it justifiable to operate again in this same case.

DR. SPITZKA asked if the cortex removed had been examined microscopically, and what was the pathological condition found.

DR. LLOYD answered that the microscopist had reported atrophy of the cortical cells.

DR. SPITZKA remarked that atrophied cells could scarcely be very potent in the production of epilepsy.

DR. LANDON C. GRAY, of New York, then presented a paper upon

THE DIAGNOSTIC SIGNS OF MELANCHOLIA,

in which he called particular attention to the difficulty of diagnosis of simple melancholia at times. It was usually, when in mild degree, confused with neurasthenia. He had recently made a study of eighteen cases of this form, and pointed out what he considered the three cardinal symptoms, viz., depression, insomnia, and post-cervical ache. The last named he thought especially characteristic. This pain was sometimes neuralgic in character, at others vague and continuous. Simple

melancholia such as this should not be confounded with neurasthenia, or melancholy states dependent upon hepatic or nephritic disease, or with non-typical forms of insanity.

DR. H. S. UPSON, of Cleveland, then read a paper in which he considered the relations between

MULTIPLE NEURITIS AND INFECTIOUS CEREBRO-SPINAL MENINGITIS.

Dr. Mills had first suggested the possibility of connection between the two. His own case was briefly as follows: A woman, aged twenty-seven, had intense pain and tenderness in the extremities together with stupor and slight opisthotonos; no electrical examination could be made because of the extreme hyperæsthesia. She had had a multiple neuritis a year before but recovered. The autopsy revealed congestion of the pia of brain and cord with marked serous effusion, and a microscopic examination of the ulnar nerve revealed interstitial inflammation there. In the opinion of the author the nerve trunk inflammation was not parenchymatous, but rather of the membranes, and was analogous to the process in the brain and cord; the nerve fibres were secondarily involved. He had not looked for bacteria.

DR. MILLS naturally felt interested in the case. He had had an autopsy on one of his own cases. Portions of nerves and sections of the brain and cord had been examined by Dr. Gray, of Washington, and this examination proved conclusively the association of neuritis with cerebro-spinal meningitis.

DR. SPITZKA referred to the vacuoles in the author's sections, and said retarded lymph outflow might be important in causing the death of tissue and the formation of gas bubbles which these vacuoles must be considered to represent. He had noted also two bodies in the sections larger than ordinary leucocytes, very delicately stained, which the author should have carefully delineated.

DR. C. K. MILLS, of Philadelphia, then gave an abstract of a paper by DR. J. T. ESKRIDGE, of Denver, on a

CASE OF ABSCESS OF THE BRAIN; OPERATION; DEATH ON THE NINTH DAY.

The patient had had typhoid fever. Two months later there was purulent inflammation of the middle ear, and not long after symptoms of brain irritation followed, such as headache, delirium, persecutory delusions together with paralysis of the right hand and right angle of the mouth. The skull was trephined over the face and hand centres, and a purulent inflammation was found under the dura. The wound was then dressed and the patient died nine days later. A widespread suppurative meningitis was found at the autopsy. Dr. Mills thought the case of great practical value. He thought trephining should have been performed in two places, at the centre which had been properly localized and also over the mastoid region where the inflammatory process had originated.

DR. B. SACHS, of New York, presented a paper on the

PERONEAL FORM OF PROGRESSIVE MUSCULAR ATROPHY.

The author reiterated his statement of last year that this form was closely related to Duchenne's type. He gave very full details of the cases of two brothers that had recently come under his observation through the kindness of Dr. Gibney. The boys were thirteen and ten years of age. There was a gradual development of double clubfoot in both at the age of five years, followed by an atrophy proceeding upward, beginning in the leg and toe muscles and spreading to those of the thigh; in one case also involving muscles of the upper extremities. The knee-jerks were present. In one there was general anæsthesia, in the other paræsthesia. There was full degenerative reaction in some of the muscles in one boy, partial in the other. The progressive wasting rendered treatment of this form of clubfoot less satisfactory than that of congenital cases. He would suspect this peroneal form in all cases where acquired clubfoot was associated with progressive wasting of the leg muscles, and particularly if heredity or family occurrence of the disease could also be established.

DR. SINKLER could recall several similar cases, one in particular of two brothers. But doubtless more would be seen if careful attention were paid to the matter.

DR. BIRDSALL did not think the presence of knee-jerk so important a diagnostic point as the author seemed to regard it. He had seen a few cases of old poliomyelitis where the paralysis and atrophy were below the knee, and yet the knee-jerks were quite active on both sides. It could not, therefore, be an essential point in diagnosis.

DR. BULLARD had also observed the presence of the knee-jerk in old cases of poliomyelitis.

DR. PRINCE asked if the author had said that the absence of pseudo-hypertrophy was a diagnostic point between this form and primary myopathies, and was answered in the affirmative. He did not consider this true.

DR. SPITZKA asked if the symmetry and the coincidence of time and intensity, as shown in the photographs, were always the case, and was answered in the affirmative.

DR. SINKLER corroborated two of the speakers as to the presence of the knee-jerk in cases of old poliomyelitis, and cited an instance from his own experience.

DR. GRAY objected to the division of progressive muscular atrophy into groups. Why should there be an arm type, a face type, a leg type? Such division might be carried out indefinitely. A more useful classification would be upon the pathology of the disease, a division into central, muscular, and peripheral nerve lesions.

DR. SACHS said he did not lay great stress upon the presence or absence of the knee-jerk. Yet, in extreme atrophy of the vasti from poliomyelitis the knee-jerk was always absent; and, if it were present, he should consider it a case of progressive muscular atrophy. He had, himself, tried to discard subdivisions as much as possible, but the present classification was a clinical necessity. A better might be made when the pathology is more accurately determined. At present there were spinal and non-spinal cases, but there was no certainty as regarded peripheral nerve cases.

DR. MORTON PRINCE, of Boston, then exhibited some microscopic specimens from the muscles of a case of

PSEUDO-HYPERTROPHY.

The patient was now twenty-eight years of age. The specimens showed a large quantity of connective tissue,

hypertrophy of a few fibres, and great atrophy of many of the fibres. There was also great loss of striation, but no fatty or granular degenerations and no vacuolization.

The meeting then adjourned.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, May 20, 1889.

THE PRESIDENT, CHARLES S. WOOD, M.D., IN THE CHAIR.

DR. T. H. MANLEY read a paper on

THE OPERATION FOR STRANGULATED HERNIA BY THE MCBURNEY METHOD, WITH REPORT OF THREE CASES.

He gave a description of the operation of McBurney, and its advantages. As far as he could learn, he was the first to report any cases of strangulated hernia, which had been dealt with by this method, and claimed that for this class of cases it seemed the ideal operation; the operative procedure consisting of a few simple principles which, if correctly understood and intelligently applied, must, generally, lead to successful results.

Briefly stated, they were—the ligating of the sac and the sewing down of the cutaneous margin of the incision to the conjoined tendon, and the aponeurotic structures, in the inguinal variety of rupture; and the securing of a dense cicatrix over the internal ring, the canal having been previously opened to this point.

Case I. was a man, æt. forty-five, who had had a hernia on his left side as long as he could remember, requiring him constantly to wear a truss. At times when his bowels were constipated and he strained more than usual at stool, the protrusion would come down under the bulb of the truss. Sometimes he would have to lie quiet a few hours before he could readily return it. On the morning before he entered Harlem Hospital, however, it came down in greater volume than ever before, and he could not return it. He came into the hospital in the evening and an immediate operation was advised, but he would not consent, thinking that he might reduce it himself, later. On the morning of the third day vomiting commenced, and he was very much reduced in strength when he asked to have an operation done.

In the afternoon he was put under ether, an incision was made from a point about the middle of that line, bounded above by the anterior-superior iliac spine and the pubic symphysis, just over the internal ring; the incision was carried downward over the inguinal canal over the protrusion to nearly the base of the scrotum. By dissecting from above, at the outset, as recommended by McBurney, the neck of the sac was first sought, and the opening continued downward till the serous covering was reached and divided. The hernia was found to consist mostly of intestine; its coat was of a dark, rather ashen hue, and was constricted at the external ring. Dr. McBurney advises that the testis and spermatic cord be left undisturbed, but in this case there was no true sac, neither was the cord or testis visible. In opening up the canal the small, atrophied, undeveloped, generative organ was found and removed. The bowel was now returned, the sac carefully dissected away from adhesions, drawn down, ligated and cut off high up, silk ligatures being employed. The borders of the incision were sewed down, on the one side to the conjoined tendon, and on the other to the fascia transversalis and the margin of the divided canal—six sutures were employed on each side; then both edges of the wound approximated by the retentive or tension sutures, the whole line of incision dusted with iodoform and carefully packed with iodoform gauze. Over this the usual dressings were applied.

The patient survived the operation but three hours. In this case it was claimed that in delaying the operation until there was profound exhaustion, and septic infection had full play, the effort to relieve him was made only as a forlorn hope, and that had an operation been done earlier he would undoubtedly have recovered.

Case II. was in a man of twenty-five, with a history similar to the preceding as regards duration. He had had hernia from boyhood, and on the day of entrance to the hospital the rupture came down, after he had made a heavy lift; and as is usual in those cases, he came for relief to the hospital only after his family physician had failed to relieve him. His hernia was on the left side, very small, not tender or very sensitive to manipulation. He suffered no pain whatever, and though an operation was advised before constitutional symptoms might arise, he declined it. The following day signs of strangulation were present, and septic infection was undoubtedly at work.

The small protrusion of the previous day had greatly enlarged. He had incessant vomiting, a very weak pulse and was greatly prostrated. It was feared, under the circumstances, that he would probably meet the same fate as the first.

His case was dealt with as was that of the man who succumbed; though owing to some difference in the anatomical arrangements of the tissues, a slight modification was made. Here the hernia was found to be congenital, the sac containing, along with the testis, a large mass of omentum and a small knuckle of intestine. As the testis was much smaller than its fellow and, probably, functionally useless, it was enucleated. In this instance a speedy recovery followed operation, and he left the hospital cured on the twenty-ninth day.

Case III. was a female, aged fifty-four, with a history of having worn a truss more than fifteen years. Her hernia was down ten days when she was brought to the hospital. She was greatly collapsed, with cold extremities and persistent vomiting. It was a question as to whether she could endure an operation. In this, as in the others, the same method of operation was undertaken. Her hernia was of the indirect, inguinal variety, following along the round ligament to the labium majus. She had a thick, fat, pendulous abdomen, requiring a very deep incision to expose the constriction, which was found just inside the ring. There seemed to be no canal of any length. The sac, which was as thin as gauze, was adherent to everything—on the outside to the connective tissue, and on the inside below to the omentum, which partly filled it. A very small portion of intestine was found tightly nipped at the point of strangulation. This woman made a good recovery, though owing to the great depth of fat in the region of incision, the tension on the sutures was so great that they gave way on the fifth day, and the borders of the wound healed by granulation.

In operating on patients with a thick layer of adipose tissue hereafter, the reporter said he would advise to dis-

pense with the suture and allow the part to close by the slower process of granulating, as in *them* the suture gave much pain, and was sure to work its way out.

Dr. Manley advised the McBurney method for every form of *strangulated hernia*, whenever or wherever found, and said that if done early, by one familiar with the anatomy of the parts, under strict antisepsis, every case should be saved, for, unlike any procedure yet advised, with it we could not only relieve the strangulation, but promise the patient a permanent cure of his hernia.

He said that in this operation we eliminated the two great dangers always to be feared with the older methods, viz., septic infection and hemorrhage. The parts being thoroughly exposed, could be completely relieved of any taint, and with the deeper structures immediately accessible, extensive hemorrhage was impossible. The operation was indeed of a most revolutionary character, and was naturally approached with timidity by those who had not tested its simplicity and great efficacy in relieving a condition which[1] Bryant says is attended with a mortality of more than fifty per cent. when sought to be relieved, even in the hands of the most experienced operators.

DR. GEORGE S. HUNTINGTON said that he had had a certain amount of experience with this operation from being associated with Dr. McBurney at the Roosevelt Hospital. The McBurney operation was especially satisfactory when performed for the relief of strangulated hernia, since, in addition to saving the patient from impending death, it afforded an excellent chance of a radical cure of his trouble. Among the particular advantages of the procedure were the open wound, with its facilities for antiseptic treatment, and the total obliteration of the sac. As to the approximation of the integument and the deeper structures—the conjoined tendon of the internal oblique and transversalis above and the transversalis fascia below—it was for the purpose of more readily accomplishing this that Dr. McBurney advocated the passage of lateral tension sutures. If the two lateral tension sutures took in at first little but the integument, there was not likely to be much difficulty, and the careful adjustment of these tension sutures had thus far given very satisfactory results. He said he should be somewhat afraid of leaving so large a wound without any sutures, for the reason that, on account of its large size, there would seem to be a probability of the cicatrix being rather weak.

DR. J. G. TRUAX said that he had the opportunity of being present at Dr. Manley's operations, and the results obtained certainly seemed very gratifying to him. The McBurney operation appeared to be a decided improvement over every other with which he was acquainted. It had been his lot to operate for strangulated hernia a few times before this method was known, and he could only say that he would have considered it a great boon had such a procedure been at his disposal.

DR. S. T. ARMSTRONG said he had noticed one point in Dr. Manley's paper which he thought called for comment, and that was the use of silk ligatures. Personally he had always employed catgut, because it was non-irritating and readily absorbed. Another point worthy of notice was in regard to congenital hernias. In a case of his own there was no spermatic cord present, but there was a mass of omentum. There the testicle was in an apparently normal condition, and it was an absolute impossibility to ligate the sac. Under the circumstances, therefore, the sac was made as tense as possible; but he could hardly hope for a successful result, as he did not have the patient's consent to remove the testicle. He would like to inquire whether Dr. Manley would feel justified in performing castration in such a case.

DR. MANLEY said that, as he had stated in his paper, different cases required different modifications of the operation. As to the character of the suture, catgut was very unreliable. When the surgeon returned the omentum to the abdominal cavity he wanted to feel sure that his ligature would not stretch or slip or allow bleeding, and personally he did not feel safe without he used silk. It was true that catgut was non-irritating and readily absorbed; but when something which was strong and would not become displaced was wanted, there was nothing like silk.

DR. ARMSTRONG explained that he referred to the ligature applied to the sac.

DR. MANLEY said that he would not mind a little irritation about the stump of the sac, because there was an open wound to deal with. As to the removal of the testicle, he would not do this without first explaining to the patient that this might be necessary for the successful completion of the operation. If the patient was assured that he would have complete virile power with the testicle remaining, he would not be apt to refuse his consent to its removal if it proved necessary.

[1] Bryant's Prac. of Surg., 3d ed., p. 307.

CORRESPONDENCE.

CULTIVATION OF ANAEROBIC BACTERIA.

To the Editor of THE MEDICAL NEWS,

SIR: In a recent number of your journal, Dr. Smith published a letter stating that the method of making anaërobic cultures proposed by me in THE NEWS of March 30th is the same as one given by Escherich in 1886. It is true we both use glass and mercury, but here the similarity ends. Escherich filled the tube with mercury, then ran in a fluid on top. I put in a solid medium, and the mercury on top. Escherich's method has the advantages and disadvantages of a fluid culture, mine of a solid culture. Escherich's method requires special apparatus, mine none. I have known and practised Escherich's method for a long time together with my own; so different are they that the two are never indicated in the same case.

My method is one for solid cultures, yet Fränkel (*Centralblatt f. Bact. u. Parasit.*, 1888, Bd. 3, p. 735) in treating of these methods does not mention Escherich's; indeed, he passes by fluid cultures as of little or no value.

JOHN A. JEFFERIS.

BOSTON.

NEWS ITEMS.

Postponement of the Meeting of the Medical Society of the State of Pennsylvania.—At a meeting of the Committee of Arrangements held at Pittsburg on July 15th, the following resolutions were adopted:

Whereas, The annual meeting of the Medical Society of the State of Pennsylvania, which convened at Pitts-

burg, June 4, 1889, was adjourned until the first Tuesday of the following September, by reason of the distress and confusion caused by the flood in the Conemaugh Valley; and

Whereas, It is the opinion of many prominent members of the Society that a successful meeting of the Society cannot be held during the present calendar year, for many reasons, the chief of which is, that the sorrow and suffering caused by the recent great calamity still oppress the entire community to such an extent as to interfere with an early meeting; therefore, be it

Resolved, That the meeting of the Medical Society of the State of Pennsylvania, which was adjourned to meet September 3, 1889, be still further adjourned until the second Tuesday of June, 1890; also,

Resolved, That a copy of these resolutions, addressed to the members of the Society, be sent by Dr. William B. Atkinson, the Secretary, to the secretaries of each Medical Society in the State, and that they be published at as early a date as possible in the medical journals of the State.

Expulsion of a Member from the Medical Society of South Carolina.—At a special meeting of this Society held July 18th, the following resolutions were adopted:

Whereas, It has been brought to the notice of the Society that Dr. T. Ballard McDow has been proven by his own confession guilty of immoral, unprofessional, and ungentlemanly conduct, and that after due notification the said Dr. McDow has failed to appear before the Society to exonerate himself from the said charges;

Resolved, That he be expelled from the Society.

2. That the Secretary be directed to publish a copy of these resolutions over his official signature in the three daily papers of this city, and in two reputable medical journals.

CHARLES W. KOLLOCK, M.D.,
Secretary of the Medical Society of South Carolina.

Dr. Brown-Sequard's Hypodermic Fluid.—The extraordinary statements made by Professor Brown-Séquard as to the efficiency of hypodermic injections of fluid expressed from the testicles of young animals in senile debility have been to a certain extent confirmed by M. Variot, who made a communication to the Société de Biologie on June 29th. The patients chosen were debilitated men, aged 54, 56, and 68 years respectively, and they were not informed of the nature of the treatment adopted. In all three cases the injections were followed by general nervous excitement, increased muscular power, and stimulation and regulation of digestion. M. Brown-Séquard said that M. Variot's observations disposed of the objection that the results he had observed in himself were due to "suggestion."—*British Medical Journal*, July 6, 1889.

The International Hygienic Congress.—We read in the *Lancet* of June 22d, that a largely attended meeting was held at the Parkes Museum of the delegates appointed by various universities, colleges, and learned societies to organize the arrangements for the International Hygienic Congress of 1891, which will meet in London. Sir Spencer Wells, who had attended the meetings of previous congresses in continental capitals, took the chair, and Dr. W. H. Corfield and Mr. Shirley Murphy, the English members of the Permanent Committee of the International Congress, acted as honorary secretaries. Dr. Corfield explained the preliminary steps that had been taken to constitute a general committee, and the following gentlemen were elected members of an executive committee with power to add to their number—Sir Douglas Galton, K.C.B., Professor Frankland, Professor Hayter Lewis, Dr. Thorne, Dr. Mapother, Dr. Mouat, Mr. E. Hart, Professor Corfield, and Mr. Shirley Murphy.

Recent Appointments in the Prussian Army Medical Corps.—Prof. E. von Bergmann has lately been appointed Surgeon-General of the First Class *à la suite* in the Prussian Army (Sanitary Corps), with the rank of Major-General; and Prof. von Esmarch, of Kiel, has had a similar distinction conferred on him.—*British Med. Journal*, June 22, 1889.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FROM JUNE 10 TO JULY 20, 1889.

FESSENDEN, C. S. D, *Surgeon*.—To proceed to Cairo, Illinois, on special duty, July 8, 1889.

LONG, W. H., *Surgeon*.—Granted leave of absence for twenty-eight days, June 18, 1889.

AUSTIN, H. W. *Surgeon*.—To proceed to Cairo, Illinois, on special duty, July 8, 1889.

IRWIN, FAIRFAX, *Surgeon*.—Granted leave of absence for ten days, July 6, 1889.

MEAD, F. W., *Passed Assistant Surgeon*.—Granted leave of absence for thirty days, June 24, 1889.

MAGRUDER, G. M., *Assistant Surgeon*.—Relieved from duty at Baltimore, Maryland, and ordered to report to the Supervising Surgeon-General for duty as Acting Chief Clerk and Attending Surgeon, July 10, 1889.

GOODWIN, H. T., *Assistant Surgeon*.—Granted leave of absence for thirty days, July 8, 1889.

VANSANT, JOHN, *Surgeon*.—When relieved to proceed to Mobile, Ala., July 11, 1889.

MEAD, F. W., *Passed Assistant Surgeon*.—Relieved from duty as Acting Chief Clerk and Attending Surgeon; ordered to St. Louis, Mo., July 11, 1889.

WILLIAMS, L. L., *Passed Assistant Surgeon*.—Relieved from duty at Cape Charles Quarantine Station; ordered to Baltimore, Md., July 10, 1889.

KALLOCH, P. C., *Passed Assistant Surgeon*.—Granted leave of absence for thirty days, July 15, 1889.

PETTUS, W. J., *Assistant Surgeon*.—When relieved to proceed to Marine-Hospital, Boston, Mass., for duty, July 18, 1889.

WOODWARD, P. M., *Assistant Surgeon*.—Granted leave of absence for thirty days, July 15, 1889.

VAUGHAN, G. T, *Assistant Surgeon*.—Relieved from duty at Boston, Mass.; ordered to Norfolk, Va., July 18, 1889.

STONER, J. B., *Assistant Surgeon*.—Granted leave of absence for twenty-five days, July 15, 1889.

GEDDINGS, H. D., *Assistant Surgeon*.—Relieved from duty at Baltimore, Md.; ordered to Key West Quarantine Station, July 18, 1889.

WENENBAUER, C. P., *Assistant Surgeon*.—Relieved from duty at Norfolk; ordered to Galveston, Texas, July 18, 1889.

GROENEVELT, J. F.—Commissioned as Assistant Surgeon, July 11, 1889 Ordered to Gulf Quarantine Station for temporary duty, July 20, 1889.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

ORIGINAL ARTICLES.

THE PREPARATION OF ABSORBABLE DRAINAGE-TUBES FROM THE ARTERIES OF ANIMALS.

BY HENRY G. BEYER, M.D., PH.D., M.R.C.S. (LOND.),
PASSED ASSISTANT-SURGEON U. S. NAVY.

EVERY surgeon will admit that the absorbable drainage-tube of Neuber, Trendelenburg, and Macewen, though very much superior to the ordinary rubber drainage-tube, has some objectionable features about it, which even its originators have freely acknowledged. It had repeatedly occurred to me that the arteries of different animals might be utilized for this purpose and be made into drainage-tubes by some suitable method of preparation, but lack of opportunity has prevented me from making any experiments with regard to it. In October last I suggested this to Professor S. H. Weeks, since which time he has interested himself greatly in the subject.

After some preliminary but highly satisfactory experiments on the lower animals, Dr. Weeks began to use them in his extensive private and hospital practice with even more success than he was led to expect from his experiments on animals. The results so far obtained by him will be found recorded in the *Transactions of the American Surgical Association* for 1889, in which the author claims these tubes to be superior to any now in use, and supports his claims by numerous examples of cases.

The absorbability and practicability of the tubes having been established in this manner, it became desirable that their method of preparation should be as much as possible perfected and elaborated. This task was assigned to me, and Dr. Weeks very kindly offered me all the necessary laboratory facilities to carry out the experiments required.

In the preparation of drainage-tubes from the arteries of animals, two things must be kept constantly in mind, namely: (1) Any method of preparation to be of value must insure the absolutely aseptic condition of the tubes as its invariable result; and (2) all the different manipulations pertaining to the method about to be described must be carried out under strictly antiseptic precautions, just as much as any surgical operation for which the tubes are intended.

The arteries to be used must be obtained fresh from the ox or cow and scrupulously examined as to their soundness. The slightest imperfection with regard to this must be deemed sufficient to eliminate them; the material is cheap, easily obtained, and plenty. The arteries coming from vigorous young cows or heifers will be found to give the best results.

As the arteries are bought from the butcher a good deal of the fatty peri-arterial tissue, together with nerves, will be found adhering to them. This tissue is easily removed by means of a pair of scissors, and the arteries, after having been freed from it, are put into a clean porcelain dish and allowed to soak in clean cold water for two hours; should the water become discolored, which is most always the case, it must be renewed as often as is necessary until it remains colorless and every little blood-clot has been washed out. Any little extra attention which is paid to this point will amply repay in the end.

After the arteries have thus been thoroughly cleaned and soaked in water, the next thing to be done is to remove as much as possible of the adventitial coat, which has become very loose and pliable by the maceration in water. For this purpose the arteries are taken out of the dish and fastened by means of tacks at both their ends on the carbolized edge of a clean table, at the same time putting them considerably on the stretch. This fibrous or adventitious connective tissue, forming the outer coat of the arteries, is now seized with the thumb and index finger of the left hand and cut away by means of a sharp pair of scissors, held in the right hand; the artery must be gone over in this manner several times, and be kept moist during this entire process by means of a sponge soaked in water until the pink musculo-elastic circular coat begins to shine through the remaining and very thin coat of adventitia. It is considered neither possible nor necessary to remove, without serious injury, every trace of the adventitial coat and the thin film which usually remains is soon absorbed; it seems to favor the growth of granulations toward the tubes, and, hence, forms a desirable rather than an objectionable feature. On the other hand, when too much of this tissue is allowed to remain, the tubes become slightly thicker than desirable, and, of course, would be absorbed more slowly.

The removal of the adventitia having been accomplished in the above-described manner, the next step to be taken is to boil the arteries for fifteen minutes in distilled water, the boiling to be done in a porcelain dish. By this means we not only harden the arteries to a certain extent by causing the thorough

coagulation of their albuminoid constituents, but we also most thoroughly sterilize their tissues. After the boiling, the arteries are placed in another porcelain dish containing a 5 per cent. solution of carbolic acid in water, and any superfluous shreds of fibrous connective tissue may easily be removed with the fingers, which must, of course, be thoroughly clean and carbolized. Holes are now cut into the coats of the arteries with a pair of sharp, clean scissors, or, better, with a punch which might be made for this purpose. An instrument like the one now used for canalization, but, of course, much smaller, would no doubt answer the purpose very well indeed, and produce openings perfectly uniform in size, a matter which cannot be controlled in free-hand cutting by means of a pair of scissors. After the holes have been cut they are preserved in a 5 per cent. solution of carbolic acid in water and kept there for the next twenty-four hours, changing the solution once or twice during that time.

If the utmost cleanliness has been observed thus far, the tubes ought to look almost white at this stage of the process, and while floating in the solution but a very thin film of fibrous connective tissue may still be seen adhering to them. After they have been thoroughly carbolized in this manner they must be drawn over glass rods of different sizes and sufficiently large to put them slightly on the stretch. This must be done very carefully and with thoroughly clean and carbolized hands. The slight stretching which they experience over the glass rods will tend to make their coats still thinner. Whatever their condition on these glass rods, whether thick or thin, it will be the state they will preserve when finished.

These glass rods, with the arteries in place, are now slipped into a long, wide-mouthed, thoroughly clean bottle containing 95 per cent. alcohol, which will need to be changed but once during the next twenty-four hours. After keeping them two hours more in absolute alcohol, they must be removed from the glass rods very carefully without being twisted; traction should be made in a straight line and with hands that are not only perfectly sterile but which must have been dipped into absolute alcohol.

From the glass rods they are immediately dropped into a wide-mouthed bottle containing the pure oil of juniper berries in quantity sufficient to keep the tubes thoroughly immersed. Here they may be allowed to remain for forty-eight hours without being disturbed. It will be seen that the walls of the tubes in this oil very soon become thoroughly transparent, assuming, at the same time, a very distinct and beautiful amber tint, not unlike that possessed by the bone-tubes of Neuber. Finally, these tubes are transferred from the oil into absolute alcohol, in which they are preserved until used.

It will be noticed that the above-described method of preparation of the arteries of animals for drainage-tubes is, with the exception of a few unessential modifications, similar to the one which is used in the preparation of bone-tubes by Prof. G. Neuber, one of the most zealous and successful promoters of antiseptic surgery in Germany, and formerly assistant to Professor von Esmarch at Kiel. Kocher's method, as practised in the preparation of catgut ligatures, was also embodied in the above method for the arteries, for the reason that experience has proved that the ligatures made according to this method are absolutely safe and thoroughly trustworthy; hence these ligatures are now used by the most experienced surgeons in preference to all others.

The oil of juniper seems to render the arteries, previously hardened in alcohol, still harder, and, consequently, makes them more efficient and serviceable than those hardened in alcohol alone. The simplicity of the method is an argument in its favor when compared with the method of preparation of drainage-tubes out of bones. It is especially advantageous that the surgeon, with but little care and expenditure of time, can make the tubes himself, needing neither chisel nor drill, and has the satisfaction of rendering them completely aseptic under his own personal supervision. Tubes of all sizes and diameters are found already formed in the animal, the thickness of these coats varying according to diameter, and both being well proportioned, one method suffices for them all, the largest requiring no more work than the smallest; they can be made of any desired length, and admit of being cut with the scissors or knife without splitting or losing their shape or contour in any way.

In conclusion, it must be mentioned that these tubes should not be allowed to remain too long in carbolized solution before being introduced into the wound, since this would cause them to swell up too much, and a few seconds' immersion is quite sufficient for the purpose of removing the few drops of alcohol which adhere to them. The process of absorption is prompt, thorough, and highly satisfactory in every respect, taking place after the manner so often described for catgut ligatures.

THE THERAPY OF OCEAN CLIMATE.[1]

BY ALBERT L. GIHON, A.M., M.D.,
MEDICAL DIRECTOR, U. S. NAVY.

THE elements of ocean climate are necessarily few: A superincumbent atmosphere free from impurities in proportion to the distance from land, with a temperature of very limited range through the absence of local disturbing agencies, and having diffused through it a correspondingly uniform amount of aqueous vapor. Nowhere over the ocean

[1] Read before the American Climatological Association, June 24, 1889.

does the mean daily fluctuation of the temperature of the surface quite amount to a degree. The temperature of the atmosphere has a rather wider range than that of the sea on which it rests, but this is very much less than anywhere on the land.

Only the weeds of the Sargasso Sea enjoy perennial abode among these simple climatic conditions. The longest passages of sailing vessels seldom extend beyond two or three months. Were they years long, the monotony would pall upon the voyager and make him sigh for the green fields and sandy plains of terra firma with all their unwholesome smells.

Next to the transitory exposure to ocean climate in the course of a sea-voyage is the residence on some small mid-ocean island where there are few vicissitudes of weather, short range of temperature, and none of the physical befoulments from masses of men and animals or decaying vegetable matter. Here, even better than on shipboard, is to be found the opportunity for making ocean climatic influences available as curative measures.

The therapeutic uses of climates, as of drugs, are to be inferred from their physiological or pathogenetic effects. What is the influence of life upon the ocean on the well man-of-the-sea? He is of two orders: One the merchant sailor, who begins his career after the land-shark has left him penniless, debauched, and diseased; who is kennelled like a brute in a gloomy, filthy, unventilated forecastle, is ill-fed, scantily clad, maltreated, and overworked. What of value can be learned from his physical history beyond the general fact, that such as survive come into port after a long voyage, notwithstanding the sparse fare, exposure, dirt, neglect, and ill-usage, still strong and vigorous? Though much of this is due to a certain enforced regularity of life and the interrupted sacrifice of health at the shrines of Bacchus and Venus Porcina, much is also due to the invigorating influence of protracted exposure to sunlight and pure air in their out-door work.

Of the better class of the men-of-the-sea—the man-of-war's-man—we might expect to learn something more definite. He too is recruited from the slums of the shipping quarters, but he is required to be clean, sober, and absolutely free from disease when enlisted, and after that is well-fed, clothed, and treated, so that his medical history may be assumed to give some indication of the causes of disease to which he has been subjected; but the medical returns of the various naval services are chiefly summaries of the cases of disease and injury treated, arranged, so far as the British and American Navies are concerned, under the customary nosological classification of the London College, and consequently, indicating but little as to the precise first causes of these diseases, whether contracted during visits on shore or developed *ab origine* in well men during their sojourn upon the high seas from causes there in operation. The rheumatism of the syphilitic, for which Neptune cannot be blamed, and the rheumatism of bad weather, which is a very decided salt-water affection, usually go into one class to swell a common total. The pulmonary phthisis for which an ancestor is responsible and the phthisis which the foul, damp air of the unventilated berth-deck has developed are undistinguished, though only the latter is of statistical interest as a product of ocean pathogenesis. The fact, too, that naval medical returns include those of the naval establishments on shore as well as those afloat, prevents the identification of the strictly nautical affections, but, notwithstanding this, it is interesting to note in the last published report of the Surgeon-General of the Navy of the United States, that among a total of 8550 admissions of sick and disabled officers and men of the Navy and Marine Corps, nearly ninety per centum were included in the following few classes, to wit:

Casualties	1917
Venereal diseases	1071
Diseases of the integument	888
Malarial and other fevers	888
Affections of the nervous system	489
Diarrhœal affections	483
Rheumatism	521
Inflammatory affections of the respiratory tract	1149

the remaining 1144 being distributed over a wide range of titles of which many, as adynamia, cephalalgia, constipatio, odontalgia, etc., have no special significance. It is probable that only about one-fourth of the cases of disease occurring at sea are attributable to any of the circumstances of oceanic life, and these are almost entirely inflammatory affections of the air passages and intestinal tract, neuroses including nausea marina, and rheumatism.

It is evident there is no saving balm in salt water, which hardens the sailor against aching muscles and swollen joints, and such of their ailments as are not the results of exposure to vicissitudes of weather are caused by decks needlessly wetted for cleaning, and the overcrowding of their badly ventilated quarters—but this is man's work, not nature's. While these are characteristic affections of the men that follow the sea, these complaints are not in any sense climatic, but due to the occupation of the seaman and to local unsanitary conditions, and the greater proportion of them are avoidable. Consequently, they have no bearing upon ocean climatic therapeutics, which does not comprehend exposure to bad weather, wet and overcrowded decks, or exhaustive labor upon sails and anchors.

What then, since there are so few causes of disease in operation, may the seeker after health hope to gain by a sea-voyage or by prolonged residence on

some ocean island where all the conditions of sea-life prevail?

First, if season, course, and destination be judiciously chosen, the invalid will obtain, on a long voyage, in a comfortable sailing vessel, *rest*—of mind and body—a condition of absolute insouciance, and relief from the cares and distractions, the daily worries and anxieties of life, the interruptions and noise and turmoil and excitements which railroads, telegraphs, and newspapers bring into the very sick-room on land.

If not so completely bed-ridden (in which case he probably ought not to go to sea at all) but that he can lie in an easy chair on deck, he will be able to breathe and bathe in an air that is barren of every impurity, and with every inspiration experience a sense of pleasurable invigoration.

If sea-sickness is not an indomitable idiosyncrasy, as I have known it to be even in captains of the navy, he will, after a few days, when he "gets his sea-legs," as sailors term it, find inexpressible delight in pacing the narrow bounds of the quarter-deck, and lengthen the hours of this gentle exercise until they become whole watches long.

Once accustomed to the motion of the vessel and of the sea, nausea will give place to appetite, which is sharpened as well for old salts as land-lubbers, and the plainest food will be taken with unwonted relish, betokening improved assimilation. If care be had to overcome the usual tendency to constipation, ingestion may go on without restraint. The eagerly anticipated meal-hours become the eventful marks of the passage of time. The whilom patient eats and sleeps, and wakes to find new zest in the simple employments of the day. Rocked in the cradle of the deep, the ocean's lullaby soothes the sufferer into forgetfulness of his ills.

A long sea-voyage in temperate latitudes on board a clean, roomy vessel, well outfitted and equipped, is a judicious therapeusis for chronic invalids of almost every class; but to be effective the ship itself must be free from the dirt, dampness, and bad ventilation which, under aggravated circumstances, made scurvy, ship-fever, and dysentery actual scourges of sea-life, and in a less conspicuous degree show their effects in the rheumatism, phthisis, and diarrhœa which are needlessly frequent among sailors. Only a clean ship can be a healthy ship, and it is just as axiomatic that a foul ship will develop, breed, and transport disease. The filthy mess in the bilges of old-time men-of-war, where the heresy of naval hygiene was not permitted utterance—the putrid mixture of salt- and fresh-water, coal-dust, oil, provisions, and decomposed timber—an artificial marsh as pestiferous as any miasm-breeding quagmire on land, gave forth emanations which blackened the paint and pervaded the atmosphere, enveloping the ship with a polluted aureole that clung to her through all her course. In those days the scent of bilge-water was considered as inseparable from a vessel as the barnacles on her bottom. If naval medical officers have lacked opportunities for distinction as operators or diagnosticians, they have still fought a good fight and gained a glorious victory in the cause of true medicine in the revolution they have effected in methods of life at sea. Virulent diseases have become extinct, and the heights of sanitary independence have been gained, whence it is possible to point out the weak places through which the enemies of human health gain entrance, and at which their further passage must be prevented.

Under any circumstances, however, a ship is useful only as a temporary expedient. In the often-quoted instance of Collingwood's flag-ship, "which with a crew of eight hundred men was, on one occasion, more than a year and a half without going into port, and never had more than six on her sick-list; this result was occasioned by his system of arrangement and his attention to dryness, ventilation, etc., but above all by the contented spirit of the sailors, who loved their commander as their protector and friend, well assured that at his hands they would receive justice and kindness, and that of their comforts he was more jealous than of his own;" but the circumstances were exceptional, and in the case of confirmed invalids a too prolonged residence on board ship becomes depressing. Hence, stationary hospital-ships are not desirable where local insalubrious influences do not prevent establishing the sick on shore. Gliding over the water day after day with the consciousness of progress and the prospect of an end, however distant, is quite another matter from riding at anchor in a harbor, watching, from a sick cot, green fields and purple hills. There is something, too, in the tonic touch of earth upon one who has been very long ill at sea—some mysterious influence affecting the molecular relations of the human body, which cannot for too great a time be intermitted, so that the therapeutic advantages of cruises are only limited.

The slowly convalescent from whatever disease—from protracted fever, chronic diarrhœa, nervous asthenia—the incipient pulmonary case, the feeble, fretful valetudinarian, the overworked business man, the broken-down woman, the child with slender hold on life, if sea-sickness is controllable, will, after a few days of pleasant sailing, recover appetite, and often recuperate with marvellous rapidity. The inebriate removed from the temptation or the means of self-gratification; the not inconsiderable class of cases of sexual exhaustion and of other forms of impaired nervous power; the thousands of victims of their own follies who fill the sanataria, private hospitals, and health-resorts; the irritable *malade imaginaire*, and melancholy hypochondriac and misanthrope are especially benefited by the quiet restfulness of a long sea-voyage

in pleasant weather, when the assimilative process becomes the dominant function, and the worn brain and flaccid vessels and feeble lungs are beguiled into feeding on what will make them strong again.

Indeed, so serviceable a measure for restoring health ought, ere this, to have led to special provision for accommodating invalids—floating sanataria—sailing vessels by preference by reason of the less rapid transition to higher or lower latitudes, with auxiliary steam power to carry them across calm belts, drive a ventilating fan, operate a dynamo for electric light, and furnish steam for artificial heat and other necessary purposes—vessels provided with every needful convenience, with skilled medical attendance and nurses, and with fresh food, fresh milk, and fresh fruits—no longer problems since the day of refrigerating chambers, milch cows, and live stock. Thirty years ago the harbors of China and Manila, Rio de Janeiro and Valparaiso were crowded with splendid American clippers, whose commanding officers were veritable princes of the sea, and whose elegantly appointed apartments were capacious enough, after housing their families and guests, to allow a spare stateroom or more for some invalid stranger; but to-day one looks in vain among the great distant seaports of the world for the ensign of an American merchantman, so that there is little opportunity from this country to make long sea-voyages, save for those wealthy enough to own pleasure yachts which can answer the double purpose of sight-seeing and health-seeking. The carrying trade between Great Britain and Australia, however, requires clipper-built merchantmen of the largest class, whose cabins are nowadays arranged with the very object of accommodating invalids, who have so increased in number that it has been proposed to construct a class of *invalid ships* for their exclusive use; but there is the same objection to congregating large numbers of sick on board ship as at health-resorts or in hospitals, so that if large, well-ventilated staterooms, bath-rooms, good food, and other comforts can be obtained on board a vessel where there are few passengers, the results will be better than upon a regular invalid ship, where the very air is heavy with studied silence, and where ever-present precaution reminds the sick man that he is manacled by disease. The spectacle of pallid, helpless men and women at Madeira and Nice and similar health-resorts depresses the well and frightens the ill—as the yellow flag of the quarantined vessel causes all the sick to die and all who can get sick to do so, until every possible victim is reached.

The therapeutic agencies which operate upon the broad ocean—rest, pure air, equable temperature and moisture, and the minimum of disturbing causes, are to be found in almost as great degree on the ocean islets, where the sound of rippling springs, the sight of fresh verdure, and the scent of earth replace the monotony of the horizon-bound disk of water.

These islets are dotted over the sea—numerous in Oceanica, where distance and rare opportunities of communication place them beyond convenient and frequent access—less numerous but easily reached in the Atlantic, where midway between the continents they invite the weary broken-down sufferers in mind and body to find rest and sweet oblivious antidote for all their ills. The Azores, Madeiras, and Canaries are the chief among these "isles of the blest." The former, especially Fayal, about two thousand miles, ordinarily a pleasant fortnight's run from Boston, offer a climate so mild, that one need hardly look for a better, were it not that that better is to be found at Madeira, and a best of all at Orotava on the Island of Teneriffe, one of the group of the Canaries—*Las Canarias* of the Spanish, the *Insulæ Fortunatæ* of Roman geographers, whose mountain peaks stand above the waters like tombstones in this ocean cemetery, where a continent and its millions of Atlantean inhabitants are buried.

The Madeiras are but five hundred miles from the Azores, and the Canaries two hundred farther south, so that the way is easy to that delightful spot, which Humboldt thanked God he had lived to behold—the valley of Orotava, fit garden of another Eden, where he who would begin life anew may find everything save the vice and artificialities and malefic agencies of modern civilization. Twenty years ago I wrote of this spot, what twenty years later I reiterate:

"Here, if anywhere, reigns perpetual spring, without fogs and frosts, where the sap never dies, where rain seldom falls, winds and storm are scarcely known, and burning heat is never felt. Shut off by the high central range of mountains from the hot winds of the African coast, it is yet open to the ocean at the north, from which and the eternal snows above, it derives the moisture that secures its equality. The temperature of Orotava never falls below 50° F., nor rises above 82° F., and only attains these extremes on such rare occasions as when the thermometer marks 108° F. or falls below 0° F. at Philadelphia. Its average for a number of years has been 68.5°F., that of Madeira being 66° F.; of Rome, 61° F.; of Nice, 60° F.; of Pau, 56° F.; and of Paris, 51° F.; the first being identical with that of our own delightful autumn days, and that which is the most grateful to the body and most conducive to its well-being. But annual means are unsatisfactory indices; countries very cold in winter and hot in summer exhibiting a temperate mean, and it is, therefore, necessary to consider the distribution of heat in each month of the year. The monthly means at Orotava have been for

January	62.2° F.
February	62.1° F.
March.	64.2° F.

April	64.6° F.
May	69.4° F.
June	73.8° F.
July	76.5° F.
August	73.2° F.
September	71.8° F.
October	69.3° F.
November	68.4° F.
December	68.7° F.

A difference of only 14.4° F. between the hottest and coldest months, while at London this amounts to 26° F.; at Pau, 32.2° F.; Rome, 28.3° F.; Nice, 29° F.; and Madeira, 15.3° F.

"But it is the winter season which most concerns the invalid, and the mean temperature of the five months from November to March, from the fall of the leaves to the opening of the lilies, at Orotava is 64° F.; at Madeira, 61° F.; and at Nice and Rome, 50° F. The February of Orotava is the June of London, the May of Pau, and the April of Rome and Nice and Cannes. Stoves are necessary for comfort in Italy and the South of France; in Orotava they are unknown. Linen garments may be worn the entire year. The Guanches were naked except for the loin cloth, and one can bathe as well on the 31st of January as on the 31st of July, while at Nice even the healthy visitor finds it necessary to stipulate for apartments opening to the south and exposed to the direct rays of the sun. There are no sudden variations of temperature at Orotava. There is a fraction over two degrees per month of gradual elevation from the winter to the summer and a corresponding decrease through the autumn, and even these differences may be almost neutralized by removing one's residence from the Puerto on the seashore in the winter to the Villa, a few hundred feet higher, or to any greater elevation on the slope of the Cañadas during the summer. Moreover, the mean temperature of one day seldom differs from that of the preceding more than a degree. On rising in the morning the invalid may be sure of respiring air of the same warmth as on the foregoing day, while the hourly variations of each day are also inconsiderable, the early hours of the morning differing only 6° to 9° F. (at Madeira the difference is 12° F.), from the heat of mid-day, and the most of this occurs before nine o'clock. At Orotava doors and windows may always remain wide opened, maintaining a perfect equilibrium within and without, the advantage of which cannot be overestimated. Here the invalid may live in the open air—the air of the ocean—which is uncontaminated by the thousand emanations of a large city, his feeble lungs, lightened of most of their labor, mechanically discharging their functions and as much at rest as is possible for organs whose only complete repose is death.

"Nor is temperature the only climatal condition in which Orotava enjoys such sanitary preëminence. In point of humidity and exemption from atmospheric vicissitudes it is unequalled by other localities. It rains but forty-five days in the course of the year. At Madeira the average is seventy-three; in Rome, one hundred and fourteen. The mists which bathe the mountain crests, the streamlets that course down their sides from the line of melting snows, the vapors wafted from the ocean, and, when these are wanting, the gentle rains of the winter, furnish that due proportion of moisture which is most agreeable to man and most favorable to healthy life. There is no warring of the elements at Orotava. The barometer stands almost invariably at 30.12 in., and, according to Belcastel, it did not vary a centimetre (0.39 in.) in six months. From February to November a northeast wind prevails, strongest in March, becoming lighter in the spring, to be all summer and the greater part of the autumn only the breath of a zephyr, setting in regularly about eight o'clock in the morning and moderating the heat of the day. The vapors from the Atlantic are gathered in a thick cloud about half the height of the amphitheatre of the valley, and there held all day, like an immense parasol, intercepting the direct rays of the sun. Days entirely clear are rare, until the gentle rains of the late autumn signalize the disappearance of the clouds and the revival of vegetation. The winter passes without frost, but the white-crowned plateau of the Cañadas, seven thousand feet high, which rims the basin of the valley, and the snow-capped Peak of Teneriffe, towering five thousand feet still higher, denote its presence and add new charms to the landscape. The superiority of Orotava in the matter of hygiene over every other known resort has been set forth by M. Gabriel de Belcastel in his excellent little monograph entitled 'Les Iles Canariennes et la Vallée d'Orotava, sous le point de vue médical et hygiénique,' and his opinion is confirmed by Professor Schacht, of Berlin, in his work on *Madera und Teneriffa*. Madeira approaches it more nearly, as might be expected from its geographical proximity; but the winter of Madeira is unpleasantly chill, its humidity is greater, and the *harmattan* blows upon it from Africa. Nice and Cannes are toyed by the smiling waves of the Mediterranean, but they sleep at the foot of the Alps, and their awakening air has its home in their clouds. Naples is visited by keen north winds, coming after the deceitful caresses of the *sirocco* from the Libyan Desert, and at Rome and Florence the cold is sometimes intense, while they are often deluged by rains."

While it may be insisted that these insular sanitaria are of the earth earthy, however small their extent, their climate, for reasons already stated, is strictly oceanic, since their area is but a speck amid the surrounding waters, so that for therapeutic purposes they may be regarded as big vessels anchored for a time where the salt sea-breeze may have un-

checked sweep across them. The conditions of equability of temperature, moisture, and electric tension, and absence of ochletic poisoning, prevail here even better than on board the ocean steamship, where there is no escape from the greasy smells of the galley and the machinery, the noise of the engine, and the exasperating clatter of crowds of passengers, or on board the sailing vessel, where the contracted stateroom is apt to be befouled by emanations from the bilges.

At Madeira and Orotava the therapeutic agencies are purely climatic. The air, and light, and heat of the sun are the revivifiers. No drug lends its potency to nature's means. The vicious microbe dies for want of food. If medicinal agencies be needed, as for the rheumatic, venereal, gouty, or dermatosic sufferer, these may be found on the island of Sao Miguel, the largest of the Azores, where intensely cold and boiling waters issue, side by side, from the earth and mingle their tides, sulphurous vapors floating continually from the mouths of the hot wells and from the not inaptly termed *Boca d' Inferno* (mouth of hell), or mud crater, which tosses the semi-solid contents, that seldom overflow, about a circle of forty-five feet diameter. Here there are sulphur and saline springs in a benign climate, where the skin may be kept soft and clean, the emunctories active, the lungs filled with pure air, and the stomach with wholesome food, and if meddlesome man will leave the stopples in his vials, the road to health may be regained all the more quickly. An old friend, himself a physician, who had gone to a famous spring because, like the bewailing Psalmist, there was no health in his flesh nor any rest in his bones, and, perhaps for the same reason, complained to me that he was not allowed to depend solely upon the column of variegated salts and alkalies, which the analysts had strung out to five and six decimal places, but the resident professional brethren insisted upon supplementing a substantial dosage of iodides and bromides that put to shame nature's own infinitesimals.

So, wise in our own conceit, we stand with minim-glass and milligramme, and measure and weigh with dosimetric nicety what perchance nature only disdainfully rejects through her waste chutes—*per vias naturales*. Is it not time to stop and ask ourselves whether it be not the better part to place our patients where, amid Heaven's boundless supplies, the wiser air-cells, and bloodvessels, and lymphatics may themselves select just what they most require—where pure air and water, and good food, cooked to tempt the palate with half the art in making pretty potions to please both eye and taste, shall be the tonics to regenerate the blood till it revivify the worn-out nerves, repair the wasted tissue, and set once more in healthy play the vital machinery which animates and gives the body being? Mere drugs cannot do this, and drugs needlessly, excessively, wrongfully administered, can only retard it. The pharmacist may oftentime be idle, but the therapeutist's task will be no lighter, for climato-therapy requires sound judgment, wise and discriminating adaptation of natural agencies, and the same watchful observation of the grade of action shown by the pulse, the condition of the organic fibre, and the state of the secretions, which are the sum of the physician's duty, however huge his pharmacopœia. If he can preserve tissue from destructive change, keep the emunctories in active play, and control the pulse's fitful beat, he may patiently bide his time for those forces to exert their power, which out of the germinal vesicle make the perfected man — out of the stomach's bole, the blood's living corpuscles, and out of these the sentient flesh and conscious brain. Only the sciolist makes pretence to cure. At our best we are but care-takers. Like children playing with building-blocks, we can pile together a few elements into semblance of organic compounds, but the sublime mystery of the living cell defies us. When we can recognize just where the departure from normal cell-life begins, and shall have learned how to control the process of assimilation, we shall have conquered disease and put under subjection all but the last enemy—*death*.

THE INFLUENCE OF AN OCEAN ATMOSPHERE ON A STAID POPULATION, WITH SPECIAL REFERENCE TO PULMONARY CONSUMPTION.[1]

By A. N. BELL, M.D.,
of Brooklyn.

It is a common criticism on the vital statistics of seamen with reference to the salutary influence of an ocean atmosphere, as related to pulmonary diseases, that the subjects are always more or less selected by special examination, as in the recruiting service of the navy; or by the limitations of age, in the merchant service. The object of this note is to rebut that criticism by the vital statistics of a staid population of all ages, dwelling under the influence of what may be considered an intensified ocean atmosphere—the trade winds of the tropics, and almost at the level of the sea.

The population selected is that of Turk's and Caicos Islands, comprising an area of one hundred and sixty-nine square miles, situated between 21° and 22° north latitude and 71° and 72° 30′ west longitude. The greatest altitude is an unoccupied bluff of less than one hundred feet; a considerable portion of the shore is water-logged and swampy; little or no attention is paid to drainage; vegetation

[1] Read before the American Climatological Association, June 24, 1889.

is scant; the dwellings are, for the most part, frail structures, almost wholly devoid of sanitary conveniences; there are no sanitary requirements; the whole people seem content to depend upon the forcible atmosphere and abundance of sunshine, for both health and the means of livelihood—the dissipation of foul emanations from the soil, and water from the salt-basins.

The following is an abstract of a copy of official records:

For the ten years 1877 to 1886 the average population of Turk's and Caicos Islands has been 4732; of this number Grand Turk, the only village, extending about two miles along the shore of Turk's Island, contains about 2000. The average temperature for the period has been 83° F. Range of temperature, 75° to 90°. Strong trade winds from east-north-east to east-south-east throughout the year. The weather is never hot at night, except on very rare occasions, when the wind subsides for brief periods. Rainy weather is almost exclusively confined to March and September.

The registration of deaths for the ten years is as follows:

record was copied, and as his early return, by the way of New York, was at the time expected, it was awaited, with a view to obtaining the needful detail. He arrived, as expected, but, unfortunately, not feeling well enough to give the subject immediate attention, was soon after taken sick and died of pneumonia.

Notwithstanding, the inquiry has been pursued and the record closely scrutinized by an intelligent observer conversant with it. Mr. Joseph Hutchings, editor and proprietor of the only newspaper published in the islands, writes:

"I have lived in Grand Turk thirty-four years. I think it is one of the healthiest places on the face of the earth. There are over 2000 Turk's Islanders in the different ports of San Domingo, within seventy miles, and two-thirds of the adult deaths are from diseases contracted there, whence they come to their relations to die. I knew every one who died in Grand Turk during the ten years, and, in looking through the records, I am satisfied that the number from pulmonary consumption does not exceed three or four yearly."

By reference to the table it will be observed that the number of deaths from pulmonary diseases of all kinds during the ten years was 155. If the larger number given by Mr. Hutchings, 4, annually,

The imperfections of this table, particularly with reference to pulmonary diseases, all grouped together, have considerably delayed the use of the information—intended at the outset for the meeting of the Association a year ago. But Dr. Daniel Bascome, the only physician of the islands for about thirty years, was on a visit to England at the time the

among the 553 registered in Turk's Island during the ten years be taken as the approximate proportion from pulmonary consumption in the whole population, the ratio from that disease to that of other diseases of the lungs, will be about the same as the proportion observed in these latitudes—one-half; and the ratio of deaths from pulmonary consump-

tion to the deaths from all causes in Turk's and Caicos Islands, about seven per cent.

Moreover, it is interesting to observe, in this connection, that the proportion of deaths from diseases of the lungs to those of other diseases in the village of Grand Turk is, according to the usual wont of such diseases, considerably larger than in the Caicos—the scattered population.

Of deaths from fevers, on the other hand, the proportion in the scattered population is almost twice as large as that in the village; and Mr. Hutchings remarks, in regard to their prevalence, "very few originate here, except an occasional case of bilious fever. The Islanders who go to San Domingo contract malaria, which, strange to say, kills the blacks without fail; most of whom are young persons."

Of the large number of accidents recorded, the most prevalent is drowning—15 of the 50 registered.

"Eye diseases" are remarked upon as being especially prevalent.

Of the large number of deaths registered "senile decay," more than one-sixth of the total number of deaths, the ages at death range from 65 to 103 years, and average about 74.

Of the deaths registered from infantile diseases, under three years of age, and thirty per cent. of them under three weeks, the number is not quite twice as large as that from senile decay. Measles, whooping-cough, and thrush are the alleged chief causes.

"Throat diseases," from which thirteen deaths are registered, include bronchitis and, in the Caicos, ulcerated throat. There is no record of diphtheria.

For the rest, the table is sufficiently explicit.

On the whole, it may be remarked, the population of these islands is a staid one to an extraordinary degree and exclusive.

The place has but few visitors, and those for short periods; the sickness and death-rates are not swelled by strangers. On the other hand, these people are generally poor. They rarely leave their homes except from necessity—in search of work—and then as before stated, they visit the less healthful place, San Domingo, where they contract fever. Their occupations and regimen are alike unfavorable to strength of constitution and protection against pulmonary consumption. Yet they are exempt to an extraordinary degree, and the exemption appears to be wholly dependent upon the climatic conditions to which they are exposed.

Cremation in France.—The Municipal Council of Paris has appropriated 383,299 francs for the erection of a crematory in that city, and has levied a "cremation tax" to defray the expenses of the incineration of the bodies of those whose friends cannot afford to pay for it.

PROLAPSE OF THE WOMB, WITH ESPECIAL REFERENCE TO THE (SO-CALLED) HYPERTROPHIC ELONGATION OF THE SUPRA-VAGINAL PORTION OF THE CERVIX, WITH REPORT OF A CASE.

By LEWIS H. ADLER, Jr., M.D.,
LATE RESIDENT PHYSICIAN UNIVERSITY HOSPITAL, PHILADELPHIA, PA.

Prolapse of the womb may occur in three distinct ways: (*a*) Simple descent. (*b*) Descent from hypertrophic elongation of the infra-vaginal portion of the cervix. (*c*) Descent from hypertrophic elongation of the supra-vaginal portion of the cervix. Without a knowledge of all the kinds of prolapsus, a differential diagnosis of any one of these conditions would be impossible. Therefore, a brief description of each of the above forms may not prove uninteresting.

Simple prolapse, or, as Dr. William Goodell aptly calls it, "substantial descent of the womb," is a sagging down of the uterus as a whole, together with its appendages. The degree of displacement depends upon the weight of the organ and the amount of relaxation of its supports, ligaments, etc. It may be *partial* or *complete*—that is to say, the womb may be either within the vagina, or wholly or in part outside the vulva; in the one case constituting the *prolapsus uteri* of writers, in the other the condition called *procidentia uteri*. These terms are so often used interchangeably that it is best to avoid them and to use the descriptive terms of complete and incomplete prolapse.

The causes, both predisposing and exciting, are the same in each of these divisions of simple prolapse, the difference between them being one solely of degree and not of kind. We may, therefore, study them together.

Advanced age, laborious occupation, habitual constipation, and childbearing, predispose this condition, whilst any cause which tends to increase the weight of the organ or to weaken its support will also prove an exciting factor.

The symptoms occurring in this prolapse are manifestly present either in a greater or less degree in the other two, and may be considered better in that form of prolapsus which this paper is meant particularly to describe.

The treatment consists in replacing the organ into its normal position and in sustaining it in the same by means of supports, in the shape of the various forms of pessaries in the market, which must be adapted to the needs of each particular case. The bowels should be carefully regulated, all heavy work and straining at stool avoided, astringent vaginal injections may be used with advantage, and rest in bed is often productive of good. Any complication which may exist, such as inflammation, ulceration, or hypertrophy must receive attention.

If the primary cause of the prolapse can be ascertained and remedied, the secondary results of the same can be the more successfully combated.

The general health must be improved. Tonics, such as strychnine, iron, and quinine should be given. Ergot is often useful. Sea-bathing is advised by many.

Where the above treatment fails, surgical procedures must be tried as a final resort.

Rupture of the perineum during parturition being a frequent starting-point in the production of prolapse of the uterus, it is essential to remedy this defect whenever found to exist. Numerous operations, having for their object the narrowing or constriction of the vaginal canal, have been resorted to by various operators, such as Sims, Emmet, Schröder, and Hegar.

Sims removes a V-shaped portion of the anterior wall of the vagina by means of curved scissors, and then brings the edges together by means of silver wire sutures. The cervix is meant to fit into the pouch thus formed.

Emmet closes the pouch by running a denuded strip, as a base to the triangle, across in front of the cervix uteri. Appreciating the difficulties involved in the execution of this operation, he has since simplified it by denuding two surfaces, about half an inch square, on either side of the cervix, and a little behind the line of its anterior lip, then removing a strip from the vaginal surface in front of the uterus, about one inch long by half an inch wide, and bringing together these three points, with the effect of forming a fold in front of the cervix. Silver wire sutures are used in this operation, four or five to the inch. Schröder freshens an oval portion and secures adhesions by alternately deep and superficial sutures.

Hegar narrows the vagina by the removal of a V-shaped piece of mucous membrane from the posterior vaginal wall, the apex being carried up nearly to the cervix, the base ending at the vulva, which it includes.

The best of these operations is considered to be that of Emmet's, if there is no evident rectocele, or that of Hegar's if there is one, particularly if it drags upon the uterus.

Prolapse of the womb from hypertrophic elongation of the infra-vaginal portion of the cervix presents an entirely different condition of affairs from that we have just been discussing. It is the result of a hypernutrition of the part (Goodell). Emmet doubts the existence of such a lesion unless it be the result of a laceration of the uterine neck and os. That it exists, however, without this lesion as a productive factor, other competent judges bear testimony, amongst whom I might mention Dr. Goodell,[1] of this city, and Dr. A. W. Edis,[1] of London. The body of the uterus in this condition occupies its normal position, but the elongated cervix projects into, and occasionally fills to a great extent the whole length of the vagina, the os externum projecting at, or even beyond, the vaginal outlet. This latter condition is, as a rule, either congenital or an exaggeration of a congenital condition, and is therefore found in multiparæ (Goodell).

Hypertrophic elongation of this portion of the cervix may arise in consequence of the process of involution not taking place properly; from the stretching of the uterus when adherent to an extra-uterine cyst (Edis); the presence of fibroid tumors dragging up the uterus as they grow above the pelvic brim, etc.

The treatment in these cases is essentially operative and will be treated of in the next and last form of prolapse to which the womb is subject, viz. (the so-called)

Prolapse of the womb from hypertrophic elongation of the supra-vaginal portion of the cervix. That this form of prolapse exists is doubted by many; yet it is admitted by the majority that a change of some sort does occur in the *supra-vaginal portion of the womb*, which is supposed to be an instance of elongated cervix, but in reality *is not in the cervix proper* but in the tissues of the body of the uterus. Emmet[2] goes so far as to say that instead of there being an enlargement of the cervix, actual atrophy of the same is the rule.

Let us at this point illustrate our further remarks by a case admitted into the University Hospital in the gynecological wards of Professor Goodell, January 4th of this year.

Mrs. E. G., aged forty-six years, a German. Always was healthy. Married in 1862. Menstrual periods had been regular since the age of fourteen, when they first started. Has had two children; the first was born March 14, 1863, the second, January 30, 1865; never had any miscarriages.

The trouble for which she sought help in the hospital came on after the birth of the second and last child; when, as she describes it, the womb descended until it gradually appeared outside of the body. This labor was a tedious one, owing to the early rupture of the waters and the large size of the child. It resulted in a slight tear of the perineum. She never felt like herself after this confinement. Suffered more or less from leucorrhœa, constant bearing-down feelings, a weakness in her back and loins, and other uterine symptoms, which she attributed to getting up and working too soon. Her housework, which she had formerly done, she now found impossible to continue.

Some years ago, as near as she can remember, a

tumor began to protrude more and more from the vulva, which was preceded by painful micturition, so intense at times that the mere thought of emptying her bladder drove her wild with fear. Her physician, who was now consulted, replaced the tumor and advised an operation; but as she would not entertain the thought, he applied measures which temporarily lessened her suffering.

This state of affairs continued until the time when she made up her mind, at her physician's earnest solicitation, to seek relief by operation at the hospital.

Upon examination on admission, her condition was found to be a pitiable one. In walking she was obliged to straddle—wabble along as it were. The tumor, which at first was easily reducible, and without pain, now caused her intense suffering if only touched. Micturition and defecation were both exceedingly difficult and painful; the former especially so. The urine was constantly dribbling away, and had excoriated the skin so much that it of itself was enough to make life miserable.

The vaginal examination revealed a boggy tumor protruding from the vulva, which was evidently the infra-vaginal portion of the cervix, clubbed, and apparently much thicker than normal, but not elongated. Professor Goodell's son, Dr. W. C. Goodell, made the first examination, and succeeded in passing into the bladder, not, however, without eliciting a cry of pain from the patient, a uterine sound, the point of which could readily be felt about three-quarters of an inch from the apex of the prolapsed tumor; demonstrating clearly the presence of a cystocele. A rectocele was also found. The question now arose as to what this tumor was. That it was a prolapsus of the womb was certain—palpation and inspection clearly showing that. But which of the three forms could it be? This could not be ascertained without measuring the uterine canal, which was now done, showing a length of near six inches. Certainly it could not be an inverted uterus or a simple descent. In the one case, there would have been no uterine cavity; and, in the other, the sound could not have shown the fundus to be high up in the pelvis and a uterine canal of over five inches. If it were a simple elongation of the vaginal cervix, it, and it alone, would have composed the tumor, and it could not have pushed forward and been hidden behind a covering of the vagina, as was the case in the history just recorded. Thus by exclusion, as well as by direct evidence, the tumor was proven to be in the main composed of the so-called prolapse of the womb from hypertrophic elongation of the supra-vaginal portion of the cervix.

On the 7th of January the woman was prepared for the operation of amputation of the vaginal portion of the cervix by Hegar's method. Whilst the patient was being etherized, Professor Goodell explained to the students of the ward class present, the ways in which the removal of an infra-vaginal portion of the cervix caused a so-called supra-vaginal elongated portion of the uterus. He said it did good and promoted a cure: (1) By the hemorrhage occurring during the operation, which, depleting the womb, caused shrinkage; (2) the suppuration necessary for the repair of the womb aided in establishing a retrogressive metamorphosis, not only of the womb and its thickened mucous investment, but also of the relaxed and subinvoluted vagina, by means of which renewed strength and tonicity were given to the parts; and, lastly, that the rest in bed and the lessened weight of the cervix tended to promote a restoration of the parts to their normal condition. The patient, now fully under the influence of the anæsthetic, was placed upon the table in the lithotomy position, on the left side, a Sims's speculum was introduced and given to an assistant to hold. The womb was brought fully into view and a sound, well curved, was passed into the bladder to determine its situation in reference to the tumor. The cervix was now transfixed, as high up as possible, with a long, straight skewer, and another one was placed at right angles to it. Behind these an elastic noose of rubber tubing was tied to control the hemorrhage, after which, the redundant portion of the cervix was removed in a cone-shaped piece. Stitches of silver wire were now used, extending from the os uteri, as a centre or hub, to the outer portion of the cervix, the stitches resembling the spokes of a wheel. The sutures numbered eighteen, each of which was clamped by a perforated shot, as in the operation of lacerated cervix uteri.[1]

The patient fully recovered from the operation without any untoward symptoms. A slight rise in temperature was noted for several days afterward, but it soon returned to normal. As a matter of course, the subsequent discharge was profuse and somewhat offensive. The stitches were left in for a long time in order to promote as far as possible the retrograde change. In this case, the operation did not produce a perfect cure, and when the patient was discharged on the 26th of February, much improved in health, and with a womb measuring only three inches in depth, she was advised to come back later and have performed Alexander's operation of shortening the round ligaments.

Having thus proven that there is a condition of prolapse of the womb which at least resembles a hypertrophic elongation of the supra-vaginal portion of the cervix, we may with advantage ascertain, if possible, the true state of affairs regarding the two points of dispute, viz.: Is this condition a true hypertrophy, and does the change which we know occurs (whatever its nature may be), affect the supra-vaginal portion of the cervix?

In reference to the first question—*Is this condition a true hypertrophy?*—I think I can clearly show that it must be answered in the negative. True hypertrophy implies a change of structure incapable of speedy resolution, which is not the case in the so-called hypertrophied elongation under discussion, for there the reduction in length is remarkably rapid when once commenced.

Again, if this were a true hypertropy, would the

[1] See "Lacerated Cervix Uteri as Treated at the University Hospital, by Professor William Goodell," in the N. Y. Medical Journal, March 2, 1889.

line of demarcation between the affected supra- and the infra-vaginal portions of the cervix be as plainly marked, separated as it is, in theory only, by the vaginal wall? Most certainly not; for are they not two portions of one continuous structure?

Professor Goodell puts the question even more tersely when he says:

"Is it reasonable to suppose that a merely superficial muscular collar, such as the vaginal attachment, can act like a conjurer's ring, and, by a sort of magic, forbid deeply seated tissue-changes on one side of it from passing through to the other? Rather than be embarrassed by this difficulty," he says, "I much prefer to apply the aphorism of the schoolmen: *quod non habet, dare non potest*—a cause cannot communicate what it does not itself possess."

And he therefore concludes,

"that the elongation, if supra-vaginal, is not communicable, because it is not essentially hypertrophic."

He uses the term *essentially*, because he says:

"I am willing to concede some degree of growth, not primary, but secondary, caused by the irritation of another factor—traction—and by the stasis in the circulation induced by it."

Having thus, I hope, satisfactorily proven the fallacy of an affirmative reply to the first question, let me briefly consider the second and less important one, but one harder to comprehend—*Does the change affect the supra-vaginal portion of the cervix?* To understand clearly this phase of the subject, allow me for a few moments to digress, in order to speak of the changes which occur in the structure of the cervix during both *menstruation* and *gestation*. In the former condition, according to the observations of J. Williams,[1] it appears that at each successive recurrence of *menstruation* a complete removal of the glandular part of the mucous membrane takes place by a process of softening and molecular disintegration which commences *close to, but not in the cervix*, or, at the os internum, and advances progressively toward the fundus during the remaining days of the flow of blood. This fact is of importance, as we shall see presently. In *gestation* the alterations are, of course, more extensive. Here the size, shape, and the position of the uterus, the form and dimensions of its cavity, and the character of its cervix are changed. It is with the latter portion that we have to do. During pregnancy the cervix loses its columns and rugæ; after parturition the enlarged muscular fibres of the uterus undergo a fatty degeneration; but the cervix is affected least by this change, owing to its firmer structure and the difference between the mucous membrane lining it and the cavity of the body of the uterus, between which a marked line of distinction exists, separating the two parts at the isthmus.

[1] Quain's Anatomy, vol. ii. p. 468.

Upon these facts hinges the theory of Dr. Isaac E. Taylor, to whom the profession is indebted for first calling attention to the stability of the cervix uteri,[1] which I have shown is not effaced by gestation or by parturition; nor does the molecular change which periodically occurs in the body of the uterus affect the membrane lining the cervix, but stops short at the line of demarcation between the two separate membranes lining the uterus, as alluded to above.

I quote from Prof. Goodell's book the conclusions which he draws from Dr. Taylor's investigations. He says:

"Dr. Taylor's testimony regarding the autopsic lesions of this disease shows conclusively, if I understood him correctly, that the elongation does not affect the glandular portion of the cervix, but that portion of the womb just above the os internum, at the junction of the body with the neck. In other words, it is the supra-glandular portion of the cervix—the isthmus—which is drawn out from the corpus, and at the expense of its thickness."

Granting that the above conclusions are simply theoretical, do not the anatomical and physiological facts amply bear out the deductions? I think they do most conclusively; and whilst admitting the possibility of a hypertrophy of the supra-vaginal portion of the cervix (not primary), I think the weight of evidence proves that the condition so often recognized by the name of hypertrophic elongation of the supra-vaginal portion of the cervix, is no more or less than a simple elongation or stretching of the body of the uterus just above and including the isthmus, when in the non-involuted womb the tissues are thick, soft, and ductile.[2]

41 NORTH TWELFTH STREET.

MEDICAL PROGRESS.

Treatment of Chronic Urethritis.—In a lecture on the treatment of chronic urethritis, delivered before the Royal College of Surgeons of England by MATTHEW BERKELEY HILL, the lecturer spoke of the results obtained by the use of soluble bougies containing various drugs in amalgamation: Fifty patients had been treated with this remedy, the average number being twelve per patient, although in one case forty-eight bougies were employed. In ten a cure was effected, two were treated by rhatany; one by sulphate of zinc and belladonna; four by chloride of zinc and belladonna; and three by chloride of zinc alone.

Thallin.—Thallin, as prepared in Christy's bougies, was tried in nine cases, with the following result: None were cured, four were made worse, one was slightly benefited, and four were not improved.

Iodoform.—Iodoform bougies were not used in any

[1] Goodell's Lessons in Gynecology, 3d edition, p. 224.

[2] For a most interesting report of a case of prolapse of the uterus and bladder of fifteen years' standing, from which thirty vesical calculi were removed, see N. Y. Medical Journal, vol. xlvi. p. 737.

cases, as they are useless in chronic urethritis, and of little service in acute urethritis.

Permanganate of Zinc.—Permanganate of zinc has been used by the lecturer for several years; it was first recommended to him by Dr. Alder Smith, of Christ's Hospital; he prescribes it in all cases of urethritis, most frequently in the acute form. Notes of its use were taken in seventy cases. Ten were cured by it; in fifty-four it very greatly diminished the discharge; in four it did no good, and in two it made the discharge worse. Its use was particularly marked by the absence of any irritation. It should not be used in strong solution, one grain in eight ounces of distilled water, and should not be prescribed in conjunction with vegetable extracts, as an almost explosive mixture is thereby produced.

Sulphates.—The sulphates of zinc, alumina, copper, and iron are most efficacious in the later stages of gleet. They appear to be easily absorbed, and penetrate deeply into the inflamed tissue. The alumina and zinc salts appear to combine with the discharge without penetrating deeply in the mucous tissue. Sulphate of copper, on the other hand, penetrates deeper, and must not be used in a strong solution, as it causes slough, which leaves a scar behind it. These notes were taken by observations through the endoscope. Sulphate of iron is of no great value but usefully affects the three preceding drugs. Twenty-five cases were treated with the four sulphates, in eight it was the third remedy employed, with four cures and four improvements. Used as the first remedy it cured twice and improved twice. The rest of the twenty-five it either cured or improved, with one exception. In that no improvement was marked. The strength of the solution as commonly used is:

Sulphate of zinc . . .	30 to 40 grains.
Alum	30 to 40 "
Sulphate of iron	20 "
Sulphate of copper . .	2 "
Water	8 ounces.

Nitrates.—In using solution of nitrate of silver, small instillations are made on the points of the disease previously ascertained. The strength of the solution is from five to twenty-five grains—five to ten minims is the quantity injected. The irritation caused by this injection is unimportant. The effect passes off in a day or two, and must be repeated every third or fourth day until the granular patches no longer exist. Where induration of the submucous tissue exists as well as granular patches, these unyielding parts are stretched in the passing of the bougie before the instillation of the nitrate of silver. The nitrate of bismuth has but a restricted value as an astringent. In some cases it does good, in others none.

Chloride of Zinc.—For the value of chloride of zinc as an injection, forty-three cases were analyzed. In seventeen of the forty-three discharge ceased after its use, in nine others it diminished.

Belladonna, Opium, Cocaine.—Extract of belladonna and extract of opium, long used by the lecturer as sedatives, appear to have but small influence in that direction. Cocaine in five per cent. solution applied before the injection is thrown in, is a very efficient anæsthetic when much pain is caused by the injection. Parenthetically it was remarked that during the acute stages of gonorrhœa, when scalding is severe, the injection of ten per cent. solution of cocaine into the urethra entirely prevents the scalding pain of micturition.—*British Medical Journal*, June 29, 1889.

Treatment of Herpetic Conjunctivitis.—In cases of herpetic conjunctivitis occurring in children, the following instillation will, according to Dr. Saint-Germain, in *L'Union Médicale*, June 13th, be found most valuable. Under its use the pain quickly subsides.

℞.—Borate of soda	grs. ijss.
Sydenham's laudanum . .	gtts. v.
Distilled water	f ℥j.—M.

Cactus Grandiflorus in Cardiac Affections.—According to the *Rev. de Thér. Méd. Chir.* of June 15th, Dr. Gregory has used the cactus grandiflorus in functional valvular disturbances with great success and considers it of far greater value than digitalis in such cases. Further, he has also found it most efficacious in cardiac innervation, in strengthening weak, irregular, and tumultuous hearts, especially in cases where the patient is nervously depressed.

Gregory claims that it is an invaluable cardiac tonic, its continued use giving tone and strength to the organ. It has no injurious effect upon the digestive system, and even when used for a long period was well borne by the most delicate stomachs.

Sozoiodolates in Diseases of the Throat and Nose.—The Swiss correspondent of the *British Medical Journal*, July 6th, states the experiences of Professor Hermann Suchannek, of Zurich, with the sozoiodolates of potassium, sodium, zinc, and mercury in nasal and laryngeal disease. His observations agree with those of Fritzsche and Seifert in being very favorable to the new drugs; in particular, the writer found that sozoiodolate of potassium, in the form of powder, mixed with talc (1 to 1 or 2), is a valuable nasal insufflation in cases of chronic mucopurulent, purulent, and serous rhinitis with profuse discharge, while the sodic salt is especially useful in tuberculous or lupoid affections of the nose, fauces, and larynx. Sozoiodolate of zinc, mixed with talc in the proportion of 1 to from 12.5 to 7.5, is said to be an active stimulant of the nasal glands, and hence proves of great service in chronic hypertrophic rhinitis associated with scanty secretion and swelling of the lower turbinated bodies, as well as in cases of senile atrophy of the nasal mucous membrane, in scrofulous rhinitis, and in genuine atrophic and syphilitic ozœna. One or two applications of the zinc compound, after the local use of cocaine, often cut short attacks of acute coryza. Further, the zinc salt considerably diminishes the dryness and other unpleasant subjective symptoms in patients suffering from pharyngitis sicca. Sozoiodolate of mercury, mixed with talc in the proportion of 1 to 20 or 10, and applied by means of a brush or cotton-wool, may be recommended in syphilitic ulcers of the nasopharynx.

Treatment of Hiccough.—Dr. John I. Brinkerhoff, of Auburn, N. Y., writes to the *New York Medical Journal* of July 6th, that he has found calamus a remedy for hiccough in every case in which he has used it, including some cases of an aggravated character. A

very small quantity suffices, only enough to reach the throat when dissolved by the saliva.

Formulæ for Cornutin.—Cornutin, the new uterine hæmostatic, may be given either by the mouth or hypodermically. The following formulæ are recommended by the *Journal de Médecine de Paris*, June 16:

I. For hypodermic injection.

℞.—Cornutin . . . . . gr. ¼.
Distilled water . . . . fʒijss.
Hydrochloric acid . . . gtts. jv.—M.

Sig. One syringeful for an injection.

II. In pill form.

℞.—Cornutin . . . . . grs. 1¼.
Gum arabic paste . . . ʒj.—M.

Make into twenty pills. Sig. Two or three at a dose.

New Skin Remedies.—SCHWIMMER has lately, in the *Wiener medizinische Wochenschrift*, published the results he has obtained in certain skin diseases by the use of salol, oxynaphthoic acid, salicylate of mercury, and anthrarobin. Salol mixed with starch in the proportion of two to one he finds a very effective remedy in all forms of venereal sores and in the buboes resulting from them. Iodoform seems to have a more rapid action, but salol has the superiority of possessing no smell. The drug also appears useful in conditions of the mucous membrane of the bladder, when given internally in doses of forty-five to ninety grains distributed through the day. Oxynaphthoic acid did not give good results in venereal cases, acting as an irritant. In scabies, however, it did not irritate, and was an effective remedy. It may be mixed with chalk and soft soap, each ten per cent., with lard. It acted well also in the secondary eczema of scabies, and allayed itching in prurigo. Salicylate of mercury possesses no superiority over the ordinary remedies used in gonorrhœa and venereal sores. Given internally in doses of one and a half to two grains, it was an effective antisyphilitic drug, although apt to cause irritation of the intestine and stomatitis. Anthrarobin was found to have no beneficial effect in psoriasis, but in herpes tonsurans, eczema marginatum, and pityriasis versicolor it acted well, being mixed with collodion in the strength of one to ten.—*British Medical Journal*, June 29, 1889.

To Abort a Felon.—DR. GAUCHER, says the *Therapeutic Analyst*, in writing on the abortive treatment of felon, states that to effect this object it is sufficient to moisten slightly the painful part with a little water, and to pass over this surface a stick of nitrate of silver. In a few hours after the skin becomes black, all pain disappears and the inflammation is arrested. No dressing is required and the black color disappears in six days.

Disinfection of the Hands.—The Paris correspondent of the *British Medical Journal*, of July 6th, writes that DRS. ROUX and REYNÈS have tried the method recommended by Dr. Fürbringer, of Berlin, for disinfecting the subungual portions of the fingers with alcohol at 80° C. After thoroughly washing and brushing their hands and nails with hot soap and water, then with carbolic acid at 10 per 1,000, they scraped the subungual portions with a short, rough, thin wire, previously sterilized. The wire was then placed in gelatine, or in agar-agar. Forty-eight hours afterward the cultivations became liquefied, owing to the numerous colonies they contained. This experiment was repeated twelve times, with similar results. The authors then scraped their nails by a mechanical dry process, and after washing and brushing their hands in hot soap and water they washed and brushed them in alcohol at 80° C. After the alcohol evaporated they again washed and brushed their hands in an antiseptic solution. Out of forty experiments, aseptic results were obtained thirty-three times. Out of eight clinical attempts, these results were obtained four times. The authors conclude that the method is superior to that ordinarily employed, and may be applied with advantage in abdominal surgery and gynecology.

Treatment of Chronic Cystitis.—Chronic cystitis has been treated, with great success, by DR. V. MOSETIG-MOORHOF, of Vienna, with iodoform injections. His method of treatment is as follows:

The bladder having been previously irrigated with moderately hot water, an injection of the following emulsion should be made:

℞.—Iodoform . . . . . 50 parts.
Glycerine . . . . . 40 "
Distilled water . . . . 10 "
Tragacanth gum . . . ¼ part.—M.

Sig.—One tablespoonful to a pint of lukewarm water, well stirred, for one injection. Injections should be made every third day.—*Wiener med. Presse*, No. 29, 1889.

Therapeutic Actions of Hydrastis Canadensis.—The latest investigations concerning the therapeutic actions of hydrastis Canadensis, are probably those of DR. M. HEINRICUS, of Sweden; the results of whose experiments are quoted in the *Fortschritte der Medicin* of June 15th.

The author endeavored to determine accurately, by experiments on animals, the action of the drug upon the heart and respiration, and its contractive powers upon the uterus and vagina. In his experiments he either used injections of the pure drug or else diluted it with equal parts of a weak salt and water solution. The injections were made into the jugular vein, and rabbits the animals used. It became apparent that every injection caused a marked decrease in the pressure of blood, but the pressure is gradually regained although not reaching the previous pressure. If large doses are given the pressure sinks rapidly and soon becomes abnormally low and the animal dies. The pulse will remain frequent for some time and it is not until the blood pressure becomes abnormally low, that it begins to get uneven and slow. Cutting of both vagus nerves does not lessen the cardiac action of the drug. Heinricus concludes that hydrastis Canadensis is an active heart poison. It exerts a paralyzing influence not only upon the nervous centres of the vascular walls but also directly upon the heart. After large injections the respirations cease entirely for about ten seconds, then begin again, at first being very shallow but gradually increasing in depth. Small doses strengthen the respirations. The author failed to observe any contraction of either the uterus or vagina to follow the use of the drug.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 798 SANSOM STREET,
PHILADELPHIA.

SATURDAY, AUGUST 3, 1889.

THE PATHOLOGY OF RELAPSES.

THE rapid advances in medicine so frequently necessitate changes in our previous theories, that they often excite but little notice. Recently our conception of the pathology of relapses, so exactly defined by Gerhardt some fifteen years ago, has been shown to need extension.

Gerhardt restricted the use of the word to those repetitions of a disease occurring after complete subsidence of the first attack but not longer thereafter than the recognized incubation-time of the disease. If the second attack occurred later than this it was thought in all cases to depend upon a new infection from without. The definiteness of this conception brought about its ready acceptance. Recently, however, it has come to be believed that specific microörganisms may remain for a considerable time latent in some portion of the body, and that they may, at a much later time than Gerhardt's definition admits, gain access to the general system and occasion a "relapse" in the true sense of the term. This belief has been the outcome of the finding of specific microörganisms in various lesions, described as sequelæ, a very considerable time after the subsidence of the initial disease. Thus A. Fraenkel obtained active typhoid fever bacilli from the pus of an abdominal abscess five months after the onset of the fever. Similar observations have this year been reported by Ebermaier and Valentini.

In the case of pneumonia parallel observations have been recorded, the specific germs having been found in the lesions of meningitis, otitis, pericarditis, peritonitis, etc., which occurred as sequelæ of pneumonia. To these an interesting case has lately been added by SENATOR (*Berliner klinische Wochenschrift*, 1889, No. 24, p. 536), in which a seventeen-year-old boy, after recovery from an ordinary attack of pneumonia, developed double median otitis, which persisted for nearly three months. During this time, on two occasions, there were attacks of erysipelatous redness of the face, which could only be attributed to infection from the inflamed ears. At the end of the three months symptoms of meningitis developed and the patient passed through a well-marked attack of that malady. During convalescence from this, *pneumonia* supervened and the erysipelatous redness of the face returned. Senator considers it proper to speak of this as a *relapse* of pneumonia, notwithstanding the long interval between the attacks, for he believes that the second attack cannot be attributed to new introduction of the infectious microörganisms from without, but must be supposed to have been set up by specific microörganisms existent during all that time in the aural lesion. That the second attack was not dependent upon any residual pulmonary condition after the first attack, was not thought possible, since the left lung was affected during the first attack, the right afterward.

The importance of cases of this kind, of which so many have recently been brought to light, cannot be overestimated as elucidating the dependence of complications and sequelæ upon the same exciting cause as the initial disease. The necessity for modification of our present ideas of the limitations of true relapses is also apparent.

Senator questions whether in another way, also, our conception of a relapse is not too limited. In the consideration of relapses of infectious diseases we rightly attribute greater weight to the exciting cause than to any constitutional or local predisposition which may remain after the first attack. But how are we to regard the repeated attacks of diseases not of infectious nature? Is it proper to speak of a relapse of gout or chorea? *Apropos* of this, not as answering the question, which he admits to be impossible in the present state of our knowledge, but as being a case in point, Senator cites a very curious case of chorea gravidarum, the details of which are given by W. Ruhemann ("Ueber Chorea gravidarum"; Inaug.-Dissert., Berlin, 1889, p. 27). The patient, twenty-five years of age, who had been previously

healthy, developed pronounced chorea, affecting the face and extremities, during the fifth month of her first pregnancy. The attack subsided with the birth of the child at term. A second pregnancy was passed through without disturbance. During the third, however, a return of the chorea occurred, so violent that premature delivery had to be resorted to. In such case should greater weight be laid upon the predisposition to repetition of the disease left from the first attack, or to the supposed exciting cause, pregnancy? It seems to Senator to depend upon the comparative importance attributed to one or the other of these factors, whether such repeated attacks should be spoken of as relapses or not.

Senator leaves the subject in an unsettled condition. The old Gerhardtian idea is shown to be too limited, but as yet it is impossible to propose a thoroughly satisfactory substitute.

PERITYPHLITIS.

IN April, 1887, Dr. T. G. Morton reported a case upon which he had operated for perforative appendicitis. At that time this case was unique in two respects: it represented the first successful result from radical operation and excision of the appendix for perityphlitis, and at the same time presented the first instance of recovery from surgical interference with diffuse purulent peritonitis.

Since the recording of Morton's doubly historical case, successful radical operations for perityphlitic inflammatory affections have, in addition to several others by himself, been reported by Kibler, Dixon, Sands, Nancrede, Brenner, McMurtry, Hoffman, Wylie, Tait, Treves, Burchard, Wiener, Whitman, Hartley, and perhaps one or two others; and surgical interference with all perityphlitic inflammatory processes which have reached the purulent stage is now regarded as an established procedure. Certainly no one would to-day be justified in withholding operation if such condition could be recognized; often, indeed, when its presence could only be suspected.

It is now universally conceded that, practically, all inflammatory disorders of the cæcal region have origin in similar affections of the vermiform appendix; which latter arise, as a rule, from kinking, constriction, or irritative contents of that organ producing surrounding inflammation by contiguity, ulcerative rupture, or continuity. Perforation of the appendix is almost always caused by retention and inspissation of intestinal secretions or excretions in its lumen—very rarely indeed by true foreign bodies, such as date, cherry, or gall stones. These pathological phenomena being conceded, the question naturally arises: Should *all* cases of appendicitis, typhlitis, or perityphlitis (collectively known by the latter term) be operated upon? According to our present knowledge and experience, most assuredly, no; although it is our belief that an appendix which has once behaved treacherously is always after to be regarded as a grave menace and ever-present danger to its possessor, and that a premeditated operation for its removal would in the long run prove vastly more safe than to await the time when, regardless of the surroundings or condition of the patient, surgical interference may have become imperative. Removal of the appendix in an interval between recurring attacks should be attended with but the very slightest risks under experienced hands, but this period should never be awaited in acute cases indicating operation, for the delay to secure the lesser risk of operation would in itself be most dangerous; operation, we believe, is always less dangerous than continuance of the disease.

It is difficult to define just which acute cases come distinctly within and which are without the operative line, but no doubt can at this date assail the general conviction that all cases which have reached a recognizably purulent stage should as quickly as possible be subjected to the knife. General peritonitis arising in a person known to be subject to cæcal trouble, or supervening during a primary attack, would always more than justify instant operation. If the formation of a tumor in the cæcal region is awaited before operating, more often than not the patient will die without being given the benefit of his only chance for recovery. Other symptoms than that of tumor must often be our entire guidance.

Diagnosis is here, as in so many other abdominal affections, the stumbling-block, and in dubious cases more or less chance must direct our efforts until laggard diagnosis can be advanced to the eminent position of operative technique.

So long as the disease is in its early stages and the cæcum maintains its usual anatomical position, operative interference is simplicity itself. Let, however, the suppurative process advance until the general peritoneum and other structures have become involved, or let the cæcum be anomalously situated, and the difficulties which may beset the surgeon are

second to none in the whole range of unfortunate possibilities.

It has been conclusively shown by Treves and others that the cæcum and its appendix are invariably completely enveloped by peritoneum just as are other abdominal viscera, so that any advantages which formerly were thought to be gained by reaching that viscus indirectly cannot now be maintained, and no other than direct abdominal incision can scientifically be employed. According to Morton, the appendix is normally placed immediately beneath a point one and a half inches inside of the right anterior superior iliac spine, and the lateral incision taking this point for its centre (which has been recommended by the same surgeon) has given decidedly best satisfaction and most successful results. It has been found possible to deal with all possible complications through this incision with great facility. A subsequent small median incision may, however, occasionally prove of value for purposes of drainage, but it has been shown time and again to be absolutely impossible to deal with most peri-cæcal affections through a median incision alone.

Access having then been attained to the appendix by the lateral direct incision, that organ should invariably be exsected whether it is or is not the seat of pathological change. No operation can be called complete or radical unless this is done, for the danger of simply opening and draining a perityphlitic abscess is attested by one of Morton's cases where this was done and the case recovered, but only to again come to him several years later in the very jaws of death, with general purulent peritonitis from a second perforation of the appendix. Radical operation was then successfully performed, and the patient effectually relieved from all future danger.

In excising the appendix it has been proved abundantly sufficient simply to ligate its base close to the cæcum, and then cut it off, not attempting the impossible feat of approximating peritoneal coats over the stump, as has been recommended by theoretical writers. No more danger ensues from thus dealing with the appendix than arises from excising Fallopian tubes in the same manner.

Dealt with by early diagnosis and operation, and in conjunction with an active laxative treatment subsequently, the conditions which we have grouped as perityphlitis are so steadily being robbed of their terrors and fatality that we may anticipate shortly to find them ranked amongst those diseases most amenable to treatment and satisfactory in result.

It is, fortunately, a rare occurrence for infectious disease to get a foothold in our asylums, but the Maine institution, at Augusta, has been passing through a troublesome experience with diphtheria. The figures, as given by the *Boston Medical and Surgical Journal*, show that there have been sixty-eight cases and fourteen deaths. The trustees have ordered a thorough investigation and sanitation of the infected premises.

The American Association of Obstetricians and Gynecologists will hold its next annual meeting at the Burnet House, Cincinnati, on September 17, 18, and 19, 1889. No formal invitation will be issued to non-members, but the Association extends a cordial invitation to members of the profession who may feel interested, to attend the meeting and participate in the proceedings. The papers and discussions will embrace subjects pertaining to obstetrics, gynecology, and abdominal surgery.

The fifty-seventh annual meeting of the British Medical Association will be held at Leeds, on August 13th to 16th next, under the Presidency of Mr. C. G. Wheelhouse, of Leeds. The Address in Medicine will be delivered by Dr. J. Hughlings Jackson, that in Surgery by Mr. T. Pridgin Teale, and that in Psychology by Sir J. Crichton Browne.

Papers from this country will be read in the Section of Surgery by Dr. F. N. Otis, of New York, "A *Résumè* of the Experience of Seventeen Years in the Operation of Dilating Urethrotomy;" in the Section of Obstetrics, by Dr. A. W. Johnstone, of Danville, Ky., "On the Mechanics of Puberty;" in the Section of Otology, by Dr. Clarence J. Blake, of Boston; and in the section of Therapeutics, by Samuel E. Solly, of Colorado Springs, "On the Climate of Colorado."

The *British Medical Journal* has scored another deserved advance in its circulation, which it announces to have now reached the very large number of 15,550 copies.

We regret to learn that the *Chicago Medical Journal and Examiner* has suspended publication. The *Journal* was one of our oldest and most esteemed exchanges, and was originally started at Chicago in 1844, by Dr. J. V. Z. Blaney, as the *Illinois Medical and Surgical Journal*. Two years later Dr. S. Brainard and others were added to the editorial staff. In

1858 Drs. N. S. Davis and W. H. Byford became the editors, and its name was changed to the *Chicago Medical Journal*. In 1875 it was consolidated with the *Chicago Medical Examiner*, with Dr. W. H. Byford as editor-in-chief, and later it passed under the editorial control of Dr. Samuel J. Jones.

REVIEWS.

BRIGHT'S DISEASE OF THE KIDNEY. By ALFRED L. LOOMIS, M.D., LL.D., Professor of Pathology and Practice of Medicine, New York University Medical College, etc. Paper, 16mo., pp. 117. Detroit, Michigan: George S. Davis, 1888.

This excellent paper is one of Davis's "Leisure Library," and is much above the average of contributions to that series. The history, the morbid anatomy, and the philosophy of the diseases treated of, are discussed with sufficient detail; the diagnosis is clearly elucidated, and the pages devoted to treatment are eminently practical and trustworthy. The author makes the following division of the subject, which is in accordance with the common practice of clinicians: 1. Acute Bright's Disease. 2. Chronic Bright's Disease, including (1) Parenchymatous Nephritis, (2) Cirrhotic Kidney (Interstitial Nephritis), (3) Amyloid Kidney. While all of Dr. Loomis's views, and especially those with reference to the morbid changes in the heart-muscle most frequently encountered in Bright's diseases, will not meet with universal acquiescence, he leaves the reader in no doubt as to the positiveness with which those views are held, or as to the extensiveness of the data upon which they are based.

SOCIETY PROCEEDINGS.

AMERICAN OPHTHALMOLOGICAL SOCIETY.

Twenty-fifth Annual Meeting, held at New London, Conn., July 17 and 18, 1889.

(Concluded from page 108.)

WEDNESDAY, JULY 17TH.—AFTERNOON SESSION.

DR. H. KNAPP read a paper on

THE TREATMENT OF CARIES AND NECROSIS OF THE ORBIT.

The upper wall of the orbit is the most frequent seat of disease, and here its consequences are most dangerous. In every case of caries and necrosis of the orbit the condition of the neighboring cavities, and especially of the nose, should be carefully investigated. Foci of suppuration should be freely opened, the cavity thoroughly cleansed, and drainage established. This can be well accomplished by small silver tubes provided with flanges. Rough bone should be scraped away with a sharp spoon. Necrosed portions of bone should be removed as soon as they become loose, or when they can be detached without injury to adjacent tissues. The eyeball should be protected, and if there is insufficient closure of the lids, a plastic operation should not be postponed until the cornea becomes ulcerated from exposure.

DR. H. W. WILLIAMS, of Boston, reported a case of

MULTIPLE CYSTS OF THE IRIS OCCURRING IN BOTH EYES.

The subject was a girl, nine years of age. In the right eye there was a projection resembling a large cyst extending from the upper margin of the pupil. A similar growth projected from the temporal border. At the inner part there were two small pedunculated growths. All were of the color of the iris. In the left eye, two somewhat oval cysts filled the pupillary space. Through the square opening left in each pupil there was a little oblique vision.

DR. T. Y. SUTPHEN related a case of

SARCOMA OF THE OPTIC NERVE.

The patient was ten years of age. The tumor involved the left orbit, and was of two years' duration. It was of a mushroom shape, and sprang from the optic nerve. Its size was six inches by five and one-quarter inches and two inches thick. It was readily removed with curved scissors. As much as possible of the nerve was removed.

DR. GEORGE C. HARLAN, of Philadelphia, related a case of

EXTENSIVE VASCULAR GROWTH IN THE VITREOUS.

The patient, a woman, æt. fifty years, presented herself November 20, 1888, on account of disturbance of vision. Examination of the right eye showed the fundus to be slightly hazy, with small dull white spots about the macula, the remains of old hemorrhages, but no recent exudation. The disk was obscured by a delicate network of vessels. Otherwise there was no opacity. There was no stroma. Up to March 2, 1889, there had been several retinal hemorrhages, but there had been no change in the vascular membrane. Vision had been reduced to $\frac{20}{LXX}$.

DR. O. F. WADSWORTH, of Boston, related two cases of

EXTRACTION FROM THE VITREOUS OF PIECES OF STEEL BY THE MAGNET,

in which the piece of steel was removed by passing an electro-magnet into the vitreous through an opening in the sclera. In the second case, the operation was followed some weeks later by a separation of the retina beginning at a point opposite that at which the puncture was made.

DR. J. O. TANSLEY, of New York, reported a case in which he had performed

CORNEAL TRANSPLANTATION

for opacity of the cornea. At the first operation the opacity was not removed to its full depth, and, although the cornea cleared to a certain extent, the result was not satisfactory. The operation was, therefore, repeated, but without any improvement in vision. In both operations there was primary union of the graft, and in neither was there any inflammatory reaction.

DR. L. WEBSTER FOX, of Philadelphia, had performed the same operation in a case of opacity of the cornea, where the patient could just distinguish light from darkness. The graft healed readily without inflammatory reaction,

and the patient obtained useful vision and could almost count fingers.

Dr. Charles A. Oliver, of Philadelphia, presented

AN ANALYSIS OF SOME OF THE OCULAR SYMPTOMS OBSERVED IN SO-CALLED GENERAL PARESIS.

These observations were made on twenty well-marked cases of general paralysis of the insane. The study was limited to subjects in the so-called second stage of the disease, where the psychical symptoms had become of such a character as to necessitate control, and where motor and sensory derangement had become more or less manifest. Care was taken that each subject was seemingly free from any extraneous general disease or local disorder, and the entire study was limited to the male sex, so as to escape any conflicting and complicating changes that might appear in connection with the many diseases peculiar to the female sex. Thirty observations were made, resulting in the following summary:

1. The sensory changes described, which have been limited to unequal optic nerve degenerations, decrease of retinal circulation, with subnormal direct and excentric vision for both form and color, distinctly show lowered sensory response.

2. The motor symptoms, consisting in unequal and feeble movement of the irides, causing inequality and irregularity of pupillary areas; the peculiar form of ataxic nystagmus; the slight loss of ciliary tone, all express want of proper muscle action—true paresis.

3. The peculiarly local conditions shown in the fundus, such as the pigment massings, the crescents of absorption, the disturbed and granular condition of the choroid, etc., all indicate wear and tear of an abused and irritated organ.

4. Therefore these observations upon the ocular apparatus, which were most probably made during the second stage of the disease known as general paralysis of the insane, show not only local changes, but distinctly demonstrate that the series of sensory motor disturbances found are but the peripheral expressions of one of the many indices of gradual loss of neural strength and power in this disease.

Dr. Sutphen related

A CASE OF DOUBLE PURULENT CHOROIDITIS RESULTING FROM MENINGITIS.

February 23, 1887, was called in consultation to see G. W. B., a robust farmer, aged thirty-nine years. He had always been healthy with the exception of an occasional "bilious headache." Never had had any specific trouble. The history was, that on February 9th he came in at noon perspiring very freely; that evening he suffered with intense headache. The next morning he was apparently well, but at breakfast had a violent chill with aching of the whole body. This was followed by high fever. Leaving the breakfast table was the last that the man remembered for three months. From this time the patient rolled and tossed in bed without decided delirium, but being in a stupid condition and easily restrained. Questions were answered only after frequent repetition and the replies ran into complete incoherence. On the third day of the illness the body became quite rigid, with the head thrown backward. On the fourth day, the left hand and forearm became swollen and the right eye inflamed; the left eye became inflamed on the tenth day. Later the left foot became swollen. The swelling of the hand and foot lasted about a week and then subsided. The fever then became less violent and the general condition improved, but the mental sluggishness remained. There was no paralysis, no convulsion, no vomiting. At the end of the third week he had a slight chill, and another after he was out of bed.

At present the man is apparently in good health. He has lost none of his functions and the mind is perfectly clear. When first seen by the writer the eyes were in the following condition: No swelling of the lids; moderate pericorneal injection; cornea clear; anterior chamber normal in depth; irides slightly discolored; pupils moderately dilated, with a yellowish reflex from the anterior portion of the vitreous. There was no perception of light, no tenderness on pressure, but a marked lessening of the tension of the globe. Three days later, the anterior chamber in each eye was obliterated by pressure from behind the lens; the eyeballs being harder than normal. One week later, the anterior chamber was again restored and tension had again fallen much below the normal. From that time there was progressive atrophy of both eyes until now there is left only the greatly shrunken globes, with, of course, absolute blindness.

In this case there must have been an extension of the intracranial inflammation along the sheath of the nerves and not a forcing of the products of inflammation forward, as sufficient pressure within the cranium to produce this must evidently have become apparent by more or less paralysis.

The case is reported as a clinical contribution to this somewhat rare and obscure trouble, which is certain to be met with in the course of practice.

Thursday, July 18th—Morning Session.

Dr. C. S. Bull presented a contribution to the subject of

TUMORS OF THE ORBIT AND NEIGHBORING CAVITIES.

Case I. was an adeno-sarcoma of the lachrymal gland. It was operated on two years ago. There has been no return.

Case II. was one of abscess of the ethmoid cells, frontal sinus and orbit in a male aged forty-six years. It was opened, washed out, and drained. There was perfect healing.

Case III.—Tumor of the maxillary antrum, nasal fossa, ethmoid cells, orbit and cranial cavity. The eye was enucleated and the maxillary antrum cleaned out. A large opening was found through the orbit into the anterior fossa of the skull and through this the tumor extended. The evening following the operation the patient became comatose, and died the next morning.

Dr. Knapp thought that the report of these cases shows the necessity of early operation in all cases of tumors of the orbit or near the orbit.

Dr. B. A. Reeve, of Canada, said that in a number of these cases of empyema of the frontal sinus he had found hypertrophy of the middle turbinated bone. This is a point of importance in etiology and prophylaxis.

Dr. Bull then reported a case of

DOUBLE CHOKED DISK, DUE TO INTRACRANIAL TUMOR, WITH AUTOPSY.

The patient, a married woman, twenty-three years

of age, was seen June 30, 1888. In February, 1888, had a miscarriage and was quite ill for a couple of weeks. There was dull headache at vertex. This became more severe. During April there were occasional attacks of diplopia. During May there was failing vision. When examined, $V = \frac{18}{xx}$ in each eye. Accommodation was normal. There was no peripheral limitation of the field of vision either for form or color. There was an irregular negative scotoma for all colors. There was marked exudative neuro-retinitis with hemorrhages in both eyes. Urine proved normal on examination. The only symptoms of intracranial disease were the lesions of the optic nerve and the headache at the vertex. The diagnosis was intracranial tumor at the base of the brain. Vision rapidly failed, and by September 25th there was no perception of light. The mental faculties gradually became impaired. Right hemi-anæsthesia came on. The patient died May 5, 1889. Autopsy showed a tumor involving the corpora quadrigemina and extending to the anterior crura of the cerebellum. The growth appeared to be a glio-sarcoma.

DR. MYLES STANDISH, of Boston, reported five cases of

PARTIAL TENOTOMIES IN CASES OF NEURASTHENIA WITH INSUFFICIENCY OF THE OCULAR MUSCLES,

in which he had performed this operation on account of constant headache, inability to use the eyes, and neurasthenic symptoms. In all but one there was marked and prompt relief of the local and general symptoms by the operation.

DR. E. E. HOLT, of Portland, called attention to the

EFFECT UPON THE ACCOMMODATION OF A PATIENT'S EYE CAUSED BY LOOKING INTO THE MIRROR SET OBLIQUELY IN THE ROOM DURING THE OPHTHALMOSCOPIC EXAMINATION.

Directing the patient to look with one eye into a mirror set obliquely while the other was examined with the ophthalmoscope, an element of ease was found in making the examination and of comfort and steadiness on the part of the patient never experienced before. The eye fatigues quickly in looking at a single object. Looking into the oblique mirror gives the impression of gazing into the distance. A notable change in the pupil will be observed when the patient is directed to look at an object at the distance of the mirror and when he is directed to look at objects reflected from it.

DR. O. F. WADSWORTH, reported a case of

PARALYSIS OF THE SPHINCTER IRIDIS

without affection of the accommodation, lasting several months, and following the instillation of homatropine in both eyes.

DR. THEOBALD thought that in all such cases it is important to exclude malingering. It would be possible for the patient by the use of a weak solution to keep up the mydriasis without affecting the accommodation.

DR. S. RISLEY said that another practical explanation of such cases is the use of a pipette previously used for a solution of mydriatic for a solution which contains no mydriatic.

DR. THEOBALD called attention to

THE EMPLOYMENT OF OLEATE OF VERATRIA TO FACILITATE THE DETERMINATION OF ERRORS OF REFRACTION.

A mydriatic affords valuable aid in myopia and in hypermetropia, but in astigmatism its use is not so satisfactory. In astigmatism he had found great help from the use of a ten per cent. oleate of veratria to the temple and forehead once a day for three or four days. This seems to exert a quieting effect upon the ciliary muscle, and especially of the radiating fibres, and lessens the tendency to asymmetrical accommodation. The following rule was formulated in regard to the correction of astigmatism. When the astigmatism is according to the rule, we need correct only that which is readily made manifest. On the other hand, in astigmatism against the rule, we are warranted in correcting fully every part of the defect which can be rendered manifest.

DR. HOLT called attention to

THE INEFFICIENCY OF HYDROBROMATE OF HOMATROPINE IN CONTROLLING THE ACCOMMODATION FOR THE PURPOSE OF FITTING GLASSES.

His experience was that this drug could not be relied upon. He reported one case in which the latent hypermetropia revealed by three per cent. solution of hydrobromate of homatropine was just one-half of that revealed by a one per cent. solution of atropia.

DR. EDWARD JACKSON, of Philadelphia, had found homatropine entirely satisfactory when used properly. The instillations must be repeated at short intervals, five or ten minutes, and three or four instillations practised. The effect rapidly passes off, and the examination must be made within one or two hours. He had followed the use of homatropine by another mydriatic without alteration in the result.

DR. JACKSON now read a paper on

AMETROPIA AS DETERMINED UNDER COMPLETE MYDRIASIS.

He had examined 4000 eyes under complete paralysis, and presented the following table of his results, these were compared with results obtained by another observer without mydriasis:

	With mydriasis.	Without mydriasis.
Compound hyperopic astigmatism	40 per cent.	9½ per cent.
" myopic "	9 "	11 "
Simple hyperopic "	6 "	16½ "
Simple myopic "	2 "	24 "
Mixed astigmatism . . .	6½ "	2 "
Hyperopia	31 "	10 "
Myopia	4 "	9½ "
Emmetiopia	1½ "	17½ "

DR. W. F. MITTENDORF, of New York, related

A CASE OF AMBLYOPIA DUE TO CHLORAL HYDRATE.

His object was to put on record a case of toxic amblyopia, due to chloral hydrate. The patient had for six months been in the habit of taking from forty to sixty grains at night to induce sleep. Suspension of the drug relieved the amblyopia.

EXECUTIVE SESSION.

The following were elected

OFFICERS FOR THE ENSUING YEAR.

President.—Dr. Hasket Derby, of Boston.

Vice-President.—Dr. George C. Harlan, of Philadelphia.

Secretary and Treasurer.—Dr. Samuel B. St. John, of Hartford.

Corresponding Secretary—Dr. J. S. Prout, of Brooklyn.

Delegate to the Ex. Com. of the Congress of American Physicians and Surgeons.—Dr. John Green, of St. Louis. Alternate, Dr. D. B. St. John Roosa, of New York.

The Society then adjourned, to meet at the Hotel Katerskill, on the third Wednesday of July, 1890.

FIRST CONGRESS OF THE GERMAN DERMATOLOGICAL SOCIETY.

Held in Prague June 10 to 12, 1889.

(Specially reported for The Medical News.)

The First Congress of German Dermatologists was officially opened in Prague on Monday, June 10th, under the Presidency of Professor Peck, of the University of Prague. More than eighty dermatologists from all parts of Germany and Austria were present, as well as from America, Russia, and Japan. All the professors of the University of Prague and most of the physicians of that city were also present.

Dr. Arning, of Hamburg, read a paper on the

INOCULATION OF LEPROSY.

He gave some information about the first successful inoculation of leprosy which he made in 1884, at the Sandwich Islands, and from which he had just received news. In 1884 the Minister of the Sandwich Islands placed at his disposal a murderer who had been condemned to death, who had never had leprosy, and whose family was exempt from any hereditary contamination. In the contract he had it inscribed that the subject on which the experiment was being made would be kept for several years in a well-ventilated and healthy prison, separated from all the other prisoners, so as to exclude all subsequent accidental contamination. He implanted in several parts of the man's body fragments, of leprous skin; moreover, he inoculated leprous pus into superficial bullæ and punctures, as in vaccination. The infectious matter was derived from a small girl, nine years old, who presented a tuberculous leprosy, and who had just had a severe leprous fever. The vaccinations in the artificial blister and punctures gave negative results. On the other hand, in the fourth week after the inoculation, the disease developed itself under the form of a subacute articular rheumatism, first in the flexed portion of the left elbow (the implantation of the fragment of skin had been done on the left arm), then in all the articulations, and persisted for four months; then there appeared along the ulnar nerve characteristic swellings, which disappeared after six months. During this time there developed at the seat of vaccination, the cicatrix of which presented the appearance of a keloid, a typical leprous nodosity, of the size of a pea, in which was found an enormous number of leprous bacilli. He could not admit that they were only derived from the implanted skin, for after sixteen months this nodosity contained just as large a number. After he returned to Europe a revolution occurred in the Sandwich Islands, and the physician of the prison was displaced. This physician writes that, according to his memory, his notes having been destroyed, that the leprosy inoculated in 1884 made great progress, and from the last news, which he received in March, 1889, the patient was in a state of leprous marasmus.

This inoculation, he added, however, is not beyond objection, for the individual might have been predisposed to it from belonging to a favorable race, and living in a country where leprosy exists, and perhaps the individual or climatic predisposition is of great importance in the final success of the inoculation. This prevented him from drawing conclusions as to the inoculability of leprosy.

Dr. Neisser, of Breslau, spoke on the

IMPORTANCE OF THE GONOCOCCUS FOR THE DIAGNOSIS AND TREATMENT OF GONORRHŒA,

which microbe was discovered by himself. He recognized the existence of urethral inflammations due to physical or chemical irritants as well as the presence of other species of microbes, and has tried to establish the three following facts:

1. Is the gonococcus the real virulent agent of the disease? To this he replied affirmatively, for this microorganism is always found in contagious blennorrhagias; still it can be found associated with other microbes, but the different clinical character of these mixed infections demonstrates the specific character of the gonococcus. Lustgarten and Mannaberg have seen in certain cases of urethritis in man diplococci which very much resemble the gonococci, but from a bacteriological point of view the microörganisms were different, for these diplococci develop themselves on substances which are usually employed as cultures for microbes, while the gonococci can be cultivated only on blood serum.

2. Why is the number of gonococci not in relation with the importance of the suppuration? Suppuration being nothing else but the reaction of the mucous membrane against the gonococci, one can understand that on a second or third infection the mucous membrane will react more slowly than in a first attack, although the number of microörganisms may be very large.

3. Can one rely on the presence of the gonococcus to establish a differential diagnosis? The answer is affirmative again, for the presence or absence of the gonococcus is of great importance in certain doubtful cases, especially in those that belong to legal medicine or to the administrative hygiene of prostitutes. The infection must be combated as early as possible, without affecting the mucous membrane. This is the first and important therapeutical rule, the patient must then be treated in the acute stage, and the medical treatment must be stopped as soon as it is demonstrated that the gonococci have disappeared. Injection of nitrate of silver is the best treatment according to the author.

Drs. Steinschneider and Galewski recommend to establish a differential diagnosis between the diplococci and gonococci, Gram's method of coloring with Bismark brown being followed.

Dr. Finger, of Vienna, said that in most of his cases of blennorrhagias he had found the gonococcus present, but in other rare cases these microörganisms were replaced by other bacilli; this might have been due to the fact that the disease had existed for a long time, as we know that gonococci are to be found more especially in parts recently involved. A good clinical sign to differentiate pseudo-blennorrhagia from blennorrhagia is that

in the first case the acute symptoms are absent and even so at the very beginning.

Dr. Obex Laender, of Dresden, said that the diagnostic value of the presence or absence of the gonococcus in gonorrhœa is unquestionable, but its absence in chronic cases is not a proof that the disease is or is not more virulent; that is why he thought that in such cases urethroscopy of great service; it is also useful when the secretion has become intermittent. In any case he thought that no method ought to be used to the exclusion of the other; and as to the rational treatment, we must principally observe the alteration of the mucous membrane.

Dr. Grunfeld, of Vienna, did not think it necessary to search for gonococci; but it is necessary to make a diagnosis of the local lesions by means of the endoscope, for this allows us to know exactly what parts are really involved. As to the good results of the early injections of nitrate of silver, he indorsed what had been said by Dr. Neisser.

Dr. von Zeiss, of Vienna, thought that the gonococcus of Neisser was the real cause of gonorrhœa, but this fact has not been absolutely demonstrated; and we must be still more on our guard, since the publication of the researches of Bockhardt on pseudo-blennorrhagia. He had also observed cases in which there were diplococci, which, on staining, took up exactly the same color as Neisser's gonococci; before identifying these last, he thought it necessary to repeat the experiments before establishing definitely the absolute value of Neisser's gonococcus.

Dr. Klotz, of New York, thought endoscopy the method which when employed in the treatment of chronic gonorrhœa was attended with the most success.

Dr. Friedheim, of Leipzig, held that injections are the best mode of treating gonorrhœa, because they act simultaneously on the secretion and on the gonococci. He thought, like Dr. Neisser, that we must destroy the microörganisms without wounding the mucous membrane; for this reason he recommends salicylate of mercury 1 : 270; the salts of thallin in suspension, etc. At the beginning of the treatment he gives injections of corrosive sublimate, which are afterward replaced by injections of zinc, tannin, etc.; yet he thinks that the surest remedy in gonorrhœa is nitrate of silver.

Dr. Neisser said that endoscopy may render service, but it is very difficult of application. Urethroscopy he considered of little value.

Dr. Jacob, of Breslau, demonstrated that certain alterations of the vaginal mucous membrane in prostitutes, which have been described in M. Oberlaender's work as being of a specific nature, have not such an origin.

Dr. Pick, of Prague, read a paper on

THE TREATMENT OF ECZEMA.

He employs, to prevent the irritation of the involved parts, in the acute period, corrosive sublimated gelatine, which allows the patient to go on with his daily occupation. If the exudation is an extensive one, he applies the saponified salicylic acid plaster all over the body, and keeps it in place by bandages which are allowed to remain six or eight days in position, and the patient is allowed to get up and walk about. The dressing must be changed when the patient experiences a burning sensation. This treatment gives good results, as the affected parts are protected against external influences.

Dr. Pick also spoke on

THE TREATMENT OF LUPUS.

He presented a patient suffering from lupus who, on entering the clinic, had a number of tumors on the body; several of these were removed, but the diagnosis was not easy, and a histological examination demonstrated the presence of giant-cells and miliary tubercles.

Dr. Doutrelepont, of Bonne, said that they often find on the borders of the Rhine cases similar to the one just described, where lupus tumors very much resemble sarcomatous tumors; the finest giant-cells are found more especially in the glands, in which regions the tubercle bacilli agglomerate in greatest number. He thought that lupus can be cured if the patient be placed in good hygienic condition. All the patients while at the hospital have no return of their trouble, but as soon as they are allowed to return home the disease recurs; this he attributes to their poor social condition. He has treated several patients, who for the first five or six years have had no recurrence. The treatment which he employs consists in topical applications of corrosive sublimate; but the disease being a long-lasting one, he curettes very deeply, and from fear of a miliary tuberculosis, also cauterizes with Paquelin's cautery, and then prescribes hot fomentations. If, after the application of the corrosive sublimate and the renewal of the crust, there are still granulations presenting a bad appearance, he uses pyrogallic acid, which he replaces two or three days later by corrosive sublimate applications, and then continues this treatment, using alternately one or the other remedy, until the obtained cicatrix becomes a perfect one. Sometimes lupus will give rise to a general infection with fever, swelling of the lymphatic glands, diarrhœa, etc., but such cases are very rare.

Dr. Lesser after having well curetted the parts, cauterizes with a strong solution of nitrate of silver, which is indicated in order to prevent general infection.

Dr. Touton thinks pyrogallic acid ointment the best means to destroy the bacillus. He applies it for three days preceding the scraping or curetting; afterward he uses the corrosive sublimate solution 1 : 1000 for the first day and then the 1 : 5000 solution.

Dr. Pick, like Dr. Doutrelepont, has seen that the physical condition of poor patients became much better during their stay in the hospital; but he did not attribute this change to the better sanitary condition in which they are placed, but rather to the period of the disease. If the lupus is unique and constitutes a primary process, the best results can be obtained if the disease is immemediately removed, but if the disease depends upon a general tuberculosis, one cannot hope to do very much good. He thought that the seat of the lupus is not an indifferent one, and lupus of the nose, especially the one which involves the mucous membrane appears to him very grave. As for the treatment, he prefers ablation to scraping out, for after this operation he has seen the occurrence of a few cases of miliary tuberculosis, which rapidly terminated in death. As caustics, for the last twenty years, he has used potash with lime, which gives cicatrices without recurrence; this does not mean that there is no trouble of the recurrence of the trouble, but he has never seen it in the cicatrix itself. After the cau-

terization he used to employ a sublimated ointment, but for some time past he has allowed the crust to remain undisturbed with no bad results; when the crust falls he applies balsam of Peru.

AMERICAN MEDICAL ASSOCIATION.

Fortieth Annual Meeting, held at Newport, R. I., June 25, 26, 27, and 28, 1889.

(Specially reported for THE MEDICAL NEWS.)

SECTION OF OPHTHALMOLOGY.

DR. GEORGE E. FROTHINGHAM, of Michigan, Chairman, in opening the Section, delivered an address upon

THE NEED OF DISCUSSING OPHTHALMIC SUBJECTS,

in which he referred to some of the many still mooted points in ophthalmology requiring the exercise of the joint wisdom of the profession for their elucidation.

DR. ROBERT TILLEY, of Chicago, then read a paper entitled

WHAT CAN WE DO TO MAKE THE CENSUS OF 1890 CONTRIBUTE EFFICIENTLY TO A CLEAR CONCEPTION OF THE CAUSES OF BLINDNESS IN THE UNITED STATES.

He urged the importance of more reliable statistics as to the causes of blindness, especially as to contagious ophthalmias, and other clearly preventable diseases; that more definite knowledge in this direction was required, before the profession could advise the public as to what measures of prophylaxis should be resorted to, and how urgent was the need of their adoption; and he urged that the present opportunity for extending our knowledge in this direction should not be wholly lost.

An investigation having the scope indicated by the twenty-seven questions proposed by Magnus, though carried out only in certain most thickly settled and readily accessible parts of the country, would elicit facts of great value. The takers of the general census might ascertain the names and residences of all persons in the community who had suffered functional loss of one or both eyes, together with the general facts as to nativity, former residence, etc.; and could furnish a full list of such persons to a qualified medical man who could continue the investigation as to completeness of the blindness, diagnosis, causation, the general medical history, etc.

The Section, at Dr. Tilley's suggestion, appointed a committee to act in conjunction with a similar committee to be appointed by the American Ophthalmological Society to confer with the Superintendent of the Census, and urge any practical plan of improving the census statistics as to blindness. This action was endorsed by the general session of the Association.

DR. A. E. PRINCE, of Jacksonville, Ill., spoke of

THE PREVENTION OF PAIN AND THE IMPROVEMENT OF THE STUMP FOLLOWING EVISCERATION OF THE EYE.

He found evisceration to be an efficient substitute for enucleation, safer, and to be recommended, perhaps, in all cases where there was no suspicion of malignant disease, as likely to furnish a better stump. A serious objection had been that there was more pain after it than after enucleation. This was probably due to the involvement of the ciliary nerves in the inflammatory reaction. At all events it had been greatly diminished by thoroughly cauterizing the inner surface of the sclera, at the end of the operation, by carbolic acid.

In applying the artificial vitreous shells proposed by Mules for use after evisceration, Dr. Prince had found that, although the result was for a time satisfactory, in many cases the tissue over the shell underwent absorption, the cicatrix gave way and the shell was ultimately extruded. As the shell came away, however, its place seemed to be at least partly filled with a mass of granulations, which subsequently condensed and contracted, but in the end gave a rounded and fuller stump than was obtained when an artificial vitreous shell was not used. This observation had led him to pack the scleral cavity with iodoform instead of introducing the glass shell, and this simpler procedure had given the same satisfactory result.

DR. H. W. WILLIAMS, of Boston, spoke on the

ADVANCES IN OUR KNOWLEDGE OF SOME CEREBRAL OCULAR AND INTRA-OCULAR LESIONS, WHICH FACILITATE THE DIAGNOSIS AND TREATMENT OF IMPORTANT DISEASES.

He reported a number of cases that had fallen under his observation, mainly of brain tumor with optic neuritis, in which the diagnosis founded on the ocular symptoms had been verified by autopsy.

DR. J. L. THOMPSON, under the heading

SOME CASES OF INFLAMMATION AND ATROPHY OF THE OPTIC NERVE,

reported a series of cases allied to those of Dr. Williams.

DR. E. J. GARDNER, of Chicago, then spoke on

THE NON-SURGICAL TREATMENT OF STRABISMUS CONVERGENS.

The careful correction of all ametropia, and the continuous wearing of the correcting glasses, without resort to other measures, had been tried in a series of cases by him with complete success in a considerable proportion of cases and marked improvement in many others. He regarded orthoptic exercises, which had not been used in any of these cases, as also of considerable value, and believed that such measures should always be tried before resorting to operative interference with the eye muscles.

DR. LEARTUS CONNOR, of Detroit, read a paper upon

TOBACCO AMBLYOPIA.

Most cases of it occur, he said, in persons addicted to the use of both alcohol and tobacco in excess. It has, therefore, been claimed that alcohol, which is known to cause definite organic changes, should be held responsible for it. He reported two cases of it, quite typical, with central scotoma for colors, and lowered vision, in which the patients smoked excessively but used no alcohol. One was that of a florist, fifty-five years old. Vision had been impaired for three months, and was reduced to R. $\frac{20}{C}$, L. $\frac{18}{CC}$; but the physiological action of nitrite of amyl, proposed as a diagnostic test by Mr. Henry Power, brought it up to $\frac{20}{L}$. Complete discontinuance of the tobacco and the use of strychnia brought about a

complete restoration of the fields for color vision, and vision equal $\frac{20}{XX}$ in four months.

In the second case, a clergyman, forty-three years old, also a hard smoker, but not using alcohol, three months ago had vision equal R. $\frac{4}{CC}$, L. $\frac{20}{CC}$; and complete oval color scotoma. Under similar treatment, the color scotoma had disappeared and vision had risen to $\frac{20}{XXX}$. Both of these patients had just prior to the development of the amblyopia been subjected to mental depression under which they had lost appetite, and had taken less food and smoked more freely than usual.

Dr. Connor had been able to collect twenty-seven cases of this kind of amblyopia in users of tobacco, but not alcohol; and but one case of central amblyopia in a drinker who did not use tobacco. Then there were twenty-five cases of recovery while still using alcohol, but abstaining from tobacco. He had seen no case of the amblyopia in a woman who did not both drink and use tobacco.

DR. H. KNAPP, of New York, thought it was pretty well established that this form of amblyopia was due to a limited retro-bulbar neuritis. There were three stages presenting different ophthalmoscopic appearances, the first giving no change in the appearance of the disk, the second showing a triangular area of pallor or atrophy of the disk toward the temporal side or macula, the third showing the appearance of an ordinary simple atrophy. Recently he had found this typical triangular area of atrophy in the eye of a young lady who neither smoked nor drank. But on further examination he discovered that there was a complete coloboma of the region of the macula. So that this interesting anomaly confirmed most beautifully the observations as to the real significance of this limited area of pallor.

DR. MYLES STANDISH, of Boston, had reported a case in which this retro-ocular neuritis had been followed shortly by general paralysis from multiple alcoholic neuritis. He believed that the occurrence of the amblyopia in any case should be regarded as evidence of a tendency to peripheral neuritis in general, that required the complete discontinuance of the use of alcohol, as well as of tobacco.

DR. P. D. KEYSER, of Philadelphia, had seen a case in which each attempt to smoke caused intense nausea, but the attempt to establish a tolerance for the drug was persisted in until what seemed to be a tobacco amblyopia supervened.

DR. J. J. CHISOLM, of Baltimore, had seen this form of amblyopia in a man who smoked but half a cigar a day, because any larger amount made him sick. He could not say that the occurrence of this failure of sight depended upon the use of any certain amount, although the amount required to produce it was generally large. He had not seen it except in persons who had used tobacco many years; had seen a case in a woman who smoked regularly. Formerly he had believed that it was not produced by chewing alone, but had recently seen cases in which this was the only way that tobacco was taken.

DR. A. BLITZ had seen a case in a woman who regularly used snuff. Recovery occurred under abstinence and the use of strychnia.

DR. E. J. GARDNER had seen tobacco amblyopia in the case of a clergyman who used no liquor. In this case no decided improvement occurred until strychnia was given in doses of one-third of a grain, hypodermically, every second day. This dose at first caused no inconvenience, but as vision improved the dose had to be diminished.

DR. S. C. AYRES, of Cincinnati, reported two cases of

MYXO-SARCOMA OF THE OPTIC NERVE,

one with small round, the other with small spindle cells, which he had removed, and which had neither of them shown signs of recurrence. The eyeball was in both instances removed with the growth, though not involved in it. He also gave a full *résumé* of all previously reported cases.

DRS. P. D. KEYSER, J. A. LIPPINCOTT, and J. L. THOMPSON reported cases they had excised without subsequent return.

NEEDLESS AND ANNOYING RESTRAINTS AFTER EYE OPERATIONS.

DR. J. J. CHISOLM, of Baltimore, under this title read a paper urging that more attention should be paid to the principle of treatment, that the ordinary course of living when in health should be disturbed as little as possible during the period of recovery from surgical interference with the eye, and that the dark room, bandages, and confinement to bed are ordinarily quite unnecessary if not positively injurious after even the capital operation on the eye.

GLAUCOMA FULMINANS AFTER CATARACT OPERATIONS WITH IRIDECTOMY.

DR. P. D. KEYSER reported two cases in which after the modified Graefe operation the eyes seemed to be doing well until, in one on the fifth day, in the other on the ninth day, hemorrhage occurred and the tension rose to + 3. One eye was thus destroyed, but the other was saved by an early additional iridectomy.

RESPECTING THE DETERMINATION OF THE DEVIATIONS IN STRABISMUS, AND THEIR TREATMENT.

DR. G. T. STEVENS, of New York, urged that the method of measuring the deviation by the prism required to bring into line the double images, was superior to all other ways of estimating the amount of squint. By careful trials, diplopia could be secured in almost every case. Where the degree of squint was very high a partial correction should be secured by one or more partial tenotomies or advancements, and then an accurate determination of the remaining deviation could be made. In but few cases was the deviation purely lateral. The result to be aimed at in all cases was not simply cosmetic, an apparent straightening of the eyes, but the restoration of normal binocular vision.

DR. E. JACKSON, of Philadelphia, thought that here, as in other parts of ophthalmology, an objective test had great advantages over a subjective test; and that probably a tenotomy did good simply by crippling the muscle involved. Even a partial tenotomy may accomplish this.

Dr. A. Blitz, of Indianapolis, reported

A TYPICAL CASE OF OCULAR IRRITATION CAUSED BY CHRONIC RHINITIS, RELIEVED BY TREATMENT OF THE NASAL TROUBLE.

Soothing applications failed to benefit, but the application of the galvano-cautery to the diseased nasal tissue gave prompt relief.

PHILADELPHIA ACADEMY OF SURGERY.

Stated Meeting, June 3, 1889.

J. Ewing Mears, M.D., in the Chair.

Dr. T. G. Morton reported the following case of

COMPOUND COMMINUTED FRACTURE OF THE FOREARM; COMMINUTED FRACTURE OF THE HUMERUS; UNRECOGNIZED DISLOCATION; SUBSEQUENT SUTURE OF THE NECK OF THE HUMERUS; RECOVERY.

Fred. O., aged twenty-four, was admitted into the Pennsylvania Hospital, December 1, 1888, with a severe shock and extensive injuries, resulting from being caught in the belting of machinery. There was a compound comminuted fracture of the forearm about the middle third, the ulna was found protruding some two inches; also a comminuted fracture of the humerus which involved the elbow-joint, and extended above the middle of the bone. The protruding portion of ulna could not be reduced until after a free division of skin and a portion of bone was removed. The swelling of the arm and shoulder was so great that it was impossible to make any further diagnosis other than that of a very extensive injury of the soft parts about the shoulder and comminution of the humerus. The limb was elevated and lead water and laudanum applied; subsequently a dislocation of the head of the humerus was made out, but owing to the serious nature of the injuries of the arm and forearm no attempt was then made at reduction—some weeks later when union had taken place the head of the bone was found attached to the tissues. The arm was practically useless so far as shoulder motion was concerned. March 14, 1889, he was admitted to the Orthopedic Hospital; two days later he made a vertical incision through the deltoid down to the head, and found it so firmly attached in the abnormal position that it was not possible without the greatest risk to attempt to dislodge it. He then carried a chain saw around the bone at the anatomical neck and sectioned the shaft obliquely from below upward and then readily placed the divided end in the glenoid cavity. A rubber drain was placed in the wound, which was closed with gut sutures. The wound united promptly; a slight sinus remains. Massage and electricity have done much for the feeble muscles, now much improved, and a fair amount of motion in the shoulder has resulted—this is constantly improving. The patient has been since the operation quite free from pain and bids fair to have a very useful arm. Dr. Morton has been unable to note that any trouble has arisen from the presence of the head of the bone in its unnatural position.

Dr. Mears said that he reported a case some years ago in which he made a subcutaneous section of the neck of the bone for old subcoracoid luxation. The result was excellent. The patient had good motion and relief from pain and also from the atrophy, which was progressing at the time of the operation.

Dr. Morton said that in regard to dislocations, he had an interesting case at the Pennsylvania Hospital, where the head of the humerus was entirely broken off from the shaft and dislocated in the axilla. He made an incision and removed the dislocated head. The injury was produced by a shutter falling from a distance and striking the shoulder just below the acromion. The patient was seventy-two years of age, and some four weeks after the accident died from catarrh of the bowels.

Dr. Morton also reported a case of

DOUBLE OPERATION IN A CASE OF DOUBLE EQUINO-VARUS.

Recently, in a case of double equino-varus, he concluded to perform the double operation—the result was most satisfactory. The little patient, four years of age, was admitted to the Orthopedic Hospital May 9, 1889. He walked upon the dorsi of the feet, on which large and dense bursæ had formed. The feet were cleansed and covered with a mercuric solution 1:2000 for several days prior to the operation.

On May 12th, the Esmarch bandage was applied on the right limb. The tendo Achillis was divided; the incision on the outer side of the foot included the bursa, which was removed. A wedge of bone was then excised with the cutting pliers and the usual horizontal and vertical incisions made; on the inner side of the foot, which included all the soft tissues down to the tarsus, the anterior tibial tendon came into view and was sectioned; the tendon of the posterior wall was readily found and divided, likewise the plantar fascia and all tense tissues—no vessels required ligation. The wounds of the open incision gaped widely; the wound incident to the tarsectomy was brought together by gut sutures. The foot was brought into a normal position and placed upon a right-angle tin splint.

The left foot was at once operated upon in a similar manner by Dr. S. K. Morton. There was no pain or rise of temperature, and in a few days the child was out of bed. On the thirteenth day the dressings were removed—no swelling or irritation.

Among the cases reported at the last meeting of the Academy was a tarsectomy with tenotomy, the patient a girl of thirteen years of age, for severe equino-varus. There was no difficulty in getting the foot in a good position, and he concluded that the open incision was not necessary; subsequently, he found some disposition to the recurrence of varus, and on May 28th divided the tissues on the inner side of the foot down to the tarsus, sectioned the anterior and posterior tibial tendons and all soft structures involved. The foot promptly came into excellent relaxed position and has not since been dressed.

Dr. J. M. Barton reported a successful operation for the relief of a

CONGENITAL UMBILICAL HERNIA

in a child thirty-three hours old.

Mrs. C. of this city was delivered by Dr. John Graham on November 3, 1888, of a female child. At the request of Dr. Graham he saw the child at 1 P.M. of the same day and found a healthy-looking female child, fully developed except that the sagittal suture was still open

to the extent of half an inch. There was a tumor at the umbilicus about the size of an adult fist; it was composed of omentum and intestines, which had protruded through an opening, over two inches in diameter, in the abdominal wall. The tumor was two and a half inches in height, over three inches in diameter, and was slightly pedunculated. It was covered by a thin layer of the expanded gelatinous matter of the umbilical cord, which was as transparent as glass. The intestines and omentum could be distinctly seen through it, and after they were returned to the abdominal cavity the left lobe of the liver could also be recognized. The cord had been tied and joined the tumor about half an inch to the left of its apex the vessels of the cord could be traced running down the left side of the tumor and entering the abdomen at the extreme left of the opening and midway between its upper and lower extremities. The child appeared to be otherwise in perfect health and had already made vigorous efforts to obtain nourishment. It seemed to be free from pain, except while the intestines were being reduced, which was done with some difficulty, as the abdominal cavity seemed scarcely large enough to contain them. A pad of cotton was then placed over the umbilicus and a firm flannel bandage bound around the child.

At twelve o'clock on the following day he met Dr. Graham for the purpose of operating, permission not having been obtained before; the child was then thirty-three hours old. On removing the dressing, which had retained most of the intestines in the abdominal cavity, the hernia was immediately reproduced, but owing to the shrinking of the gelatinous tissue which formed its sac it was not as large as the day before. It now measured six and three-quarters inches in circumference and four and a quarter inches over its convexity. The covering was not quite opaque, though the abdominal contents could still be indistinctly distinguished through it; it readily broke down under the fingers and was quite offensive, requiring repeated applications of a solution of the bichloride of mercury for the comfort of the operators.

It had been their intention, if the parts were found in the same condition as the day before, to pass long harelip pins across the opening, bringing its edges together and leaving the sac on the outside to shiver and dry. As this proved on trial to be ineffectual, the entire sac was trimmed away. About half an ounce of opaque serum with flakes of lymph floating in it ran from the abdominal cavity and the bowels exposed were now highly inflamed, being of a deep red color with patches of lymph lying upon them and glueing them together. Thinking the peritonitis was probably purely local and that the rest of the abdominal cavity was protected from infection by these adhesions they were careful not to rupture them. The bowels were kept in place by an antiseptic sponge while the edges of the opening, which measured six and a quarter inches in circumference, were freshened and brought together with seven harelip pins. A space of an inch was left between two of the pins for drainage, the umbilical vessels passed through this opening and acted as drainage threads. This opening was left to prevent the damming up of any further secretion of serum or pus, which might rupture the adhesions between the bowels and cause the local peritonitis to become general. The closed wound was dusted with iodoform and dressed with mercurial gauze.

As there was great tension on the pins holding the parts together, and it seemed probable that they would ulcerate through in a few hours, two pieces of Mead's adhesive plaster, each about six inches square, were placed one on each side of the wound, with the extremities that ran toward the spine cut into many tails. They approached in front to within an inch and a half of each other and were laced together by a strong cord placed over the dressings.

Nov. 5, child doing well, cries but little, and has no fever. The wound looks well and is not offensive.

6*th*. Slight discharge of pus through opening.

7*th*. About two drachms of pus.

8*th*. Six of the pins removed, wound slightly offensive, three drachms of pus discharged.

There was but little pus after this date. The wound was kept firmly supported by the plaster for two weeks and was dressed daily; as it was then firmly healed, it needed no further attention. The resulting scar is three and a half inches long. This condition, in a slight degree, is not very rare, but he was not aware of any case where the hernial protrusion was so extensive, except one reported as a "Laparotomy in a Child Sixty Hours Old," by Dr. Stolypinski in the *Centralblatt für Gynäkologie*, for March, 1889. The operation was performed at the clinic of Prof. Phaenomenoff, of Kassan, Russia. The tumor in this case was the size of a goose-egg, but the hernial opening was quite small, making it difficult to reduce the intestines, but there appeared to be no difficulty in retaining them after they were reduced. The opening was closed with silk and catgut. This child also made a good recovery.

NEW YORK ACADEMY OF MEDICINE.

SECTION OF PÆDIATRICS.

J. LEWIS SMITH, M.D., CHAIRMAN.

Stated Meeting, May 11, 1889.

DR. FOREST exhibited a child two and a half years of age which was unable to stand, walk, or creep, owing to

GENERAL MUSCULAR PARESIS.

There was no history of a previous severe illness. Dr. Forest was inclined to attribute the muscular insufficiency to a narrow prepuce, which he intended to dilate.

DR. SEIBERT said that in his opinion the muscles become atrophic from a permanent bilateral brain trouble in consequence of meningitis in early life.

DR. A. JACOBI remarked that he would not formulate an opinion, as all would be guess-work in the absence of a history of the case presented. He would state, however, that he had never known a case of paralysis, paresis, or insufficient development cured by dilating the prepuce.

DR. J. LEWIS SMITH said that there are cases on record of muscular paresis cured by dilating the prepuce. He distinctly remembered one case in which a child dragged one leg and was almost unable to walk, and soon got into a normal condition after dilating its narrow prepuce.

DR. FOREST then read a paper on

RETRO-PHARYNGEAL ABSCESS,

embracing chiefly the diagnosis, symptomatology, and treatment of the affection. He cited a number of cases observed, and gave a detailed account of one case of

collapse after incision. Although breathing was entirely suspended, he first cleared the throat of pus and then employed artificial respiration. The abscess did not refill and the child died of exhaustion on the following day. In conclusion, he stated that such abscesses are to be looked upon as suppurating lymphadenitis, and the diagnosis is best made by the finger.

Dr. Koplik had observed about twenty-five cases, in many of which a previous angina was noticeable. He would not sanction the introduction of the finger as a means of diagnosis, as sudden deaths have been reported from rupture of the pus sac. He uses a tongue depressor and makes an oblique incision which will not readily heal up, thus preventing reäccumulation of pus.

Dr. Seibert spoke of the snoring respiration as one of the marked symptoms of retro-pharyngeal abscess. The formation of such abscesses is invariably due to infection. When incising an abscess which is situated low down in the pharynx, he is in the habit of placing the child so that its head is lower than the body. As a rule, such abscesses refill several times.

Dr. Caillé remarked that within the last few years he has invariably punctured a pus sac in the pharynx, if accessible from the mouth, by means of a blunt instrument in order to avoid the speedy closure of an incised wound. The best instrument for the purpose is an ordinary depressing forceps which is pushed into the fluctuating swelling, after which the branches of the forceps are pressed apart, thus creating a ragged wound not liable to close.

Dr. Jacobi said that if any one sign was characteristic of retro-pharyngeal abscess it was a peculiar voice, which he would call "tin voice," which he never found mentioned in the text-books. When puncturing an abscess the child should be held upright and thrust forward as soon as the incision is made. If the incision is made with the head low there is danger of aspirating pus. He was recently called to operate upon a child which had been cyanotic all day from the pressure of the pus. On introducing his finger for the purpose of locating the swelling the child collapsed, and was dead. An incision was made at once and artificial respiration resorted to without avail. In all probability the child had aspirated pus all day long and was in a dying condition when he introduced his finger.

Dr. J. Lewis Smith remarked that he had never seen retro-pharyngeal abscess in a child over two years of age. In puncturing an abscess he would place the child upon its side face downward and he would always use the finger as a means of diagnosis.

Dr. A. F. Currier read a paper on

VULVO-VAGINITIS IN CHILDREN.

(See The Medical News, July 6, 1889, page 3.)

Dr. A. Jacobi said that inasmuch as a mucous surface must be denuded of epithelium to make infection possible, we shall find a simple catarrh to be the starting-point for every infectious vulvo-vaginitis. In treating by antiseptics it must be borne in mind that corrosive sublimate and boracic acid have no soothing action.

Dr. Koplik said that the majority of cases are simple in nature and the gonorrhœal forms are rare. He was convinced that the secretion from a simple form of vulvo-vaginitis could produce violent conjunctivitis. As regards treatment he uses a wash of tannin and alum in water and swabs the vagina twice a week with a ten per cent. solution of nitrate of silver.

Dr. Weeks said that a healthy mucous membrane can absorb infectious matter, and whenever we have pus we have infection. The micrococcus flavus is similar in appearance to the gonococcus and the latter is very common. A two per cent. solution of silver nitrate is a good germicide, a ten per cent. solution destroys epithelia and is entirely too strong. He had treated eighteen cases with sublimate 1 : 2000 with very good results.

Dr. Seibert said that the fact that girls with leucorrhœa marry and do not infect their husbands speaks against the gonorrhœal origin of the majority of cases.

Dr. Weeks replied that in every case of ophthalmia of the newborn the gonococcus is found. The infection takes place from the woman and in many cases the man is absolutely free from disease—thus the man not being infected is no proof of the woman not harboring the gonococcus.

NEWS ITEMS.

The College of Physicians and Surgeons of Baltimore.—The Faculty of the College of Physicians and Surgeons of Baltimore have filled the vacancies created by the deaths of Profs. John S. Lynch and Oscar J. Coskery and the retirement of Prof. A. B. Arnold as follows: Prof. Thos. S. Latimer has been transferred to the chair of Principles and Practice of Medicine and Clinical Medicine; Prof. Chas. F. Bevan to the chair of Principles and Practice of Surgery and Clinical Surgery; Prof. J. W. Chambers to the chair of Operative and Clinical Surgery, and Prof. George H. Rohé to the chair of Obstetrics and Hygiene. To fill vacancies created by these transfers new professors were elected as follows: Prof. Henry Sewall, of the University of Michigan, to the professorship of Physiology; Dr. George J. Preston to the professorship of Anatomy, with the Diseases of the Nervous System as a clinical branch of instruction. As an evidence of esteem on the part of his colleagues, Prof. Arnold was elected emeritus professor of Clinical Medicine on his retirement.

Pasteur's Latest Returns.—We quote the following latest returns of Pasteur's Institute from *L'Union Médical*, July 4, 1889:

From May 1, 1888, to May 1, 1889, 1673 persons, bitten by rabid or presumably (*très suspects de rage*) rabid dogs, had been treated, 1487 being French and 186 foreigners. Of this total number, 118 were bitten on the head or face. Six cases, four of which had received bites on the head or face and two on the limbs, were attacked with rabies during the treatment and died; four others developed the disease within a fortnight after leaving the Institute, the treatment having been discontinued. Three patients died of rabies after the complete conclusion of the treatment, and these, therefore, represent the number in which the treatment actually proved unsuccessful—a ratio of 1 in 554. If, however, one should also include the ten other deaths, "which," Dr. Pasteur naively adds, "would be illogical," the mortality would still only be 1 in 128.

The Rejuvenescence of Elderly Women.—Dr. Brown-Séquard, in concluding a communication to *The Lancet*,

July 20, 1889, on the effects produced on man by the subcutaneous injections of testicular liquid, states that "there are good reasons to think that subcutaneous injections of a fluid obtained by crushing ovaries just extracted from young or adult animals, and mixed with a certain amount of water, would act on old women analogous to that of the solution extracted from the testicles injected into old men."

It would be interesting to learn, also, the physiological effects upon old women of injections of the testicular liquid, and conversely of the effects upon old men of injections of the ovular.

An Insanitary Exhibition.—The practical sanitation at the Paris Exhibition is harshly and deservedly criticised. In some of the large restaurants attached to the exhibition the water-closets are in the middle of the kitchens! A less dangerous expedient for economizing space might have been found, and one which would not have thus outraged all sense of decency, common cleanliness, and the elementary precepts of hygiene.—*British Med. Journal*, July 20, 1889.

Connecticut's Health Statistics.—The annual report of the State Board of Health for the past year has just been presented to the General Assembly. According to the death-rate, the State is in about the same condition of healthfulness as 1887. The rate is between seventeen and eighteen in a thousand, which is lower than that in many States, and also lower than in Europe. The Board predicts that the malaria—which is decreasing, especially in Fairfield County, where it originated—will ultimately disappear. Typhoid fever is increasing, as are diarrhœal diseases. Whooping-cough and meningitis are proving more fatal, while croup and diphtheria are less so. An investigation is being made into the drinking water of the State. An analysis has already been made of the waters of seventeen of the largest cities and towns. Hartis found to have the best water thus far.

The Utilization of Garbage.—According to the *Bulletin of the Rhode Island State Board of Health* for May, the city of Milwaukee will soon abandon the cremation of garbage, which it was among the first of the western cities to adopt and advocate. It is proposed to substitute a dry process in the place of combustion. A company is at work with a new method which converts cities' refuse into articles more or less salable. The garbage is made to pass through a series of mechanical driers, and in the course of ten hours becomes a brown powder. The oil is pressed out or drawn off, and the residue can be sold as a fertilizer.—*N. Y. Med. Journal*, June 29.

NOTES AND QUERIES.

THE POSTPONEMENT OF THE MEETING OF THE PENNSYLVANIA STATE MEDICAL SOCIETY.

To the Editor of THE MEDICAL NEWS,

SIR: At the regular meeting of the Medical Society of the State of Pennsylvania, held in Philadelphia in June, 1888, it was resolved to hold the next annual meeting of the Society in Pittsburg, on the third Tuesday of May, 1889, and the Committee of Arrangements afterward assumed the responsibility of changing that day to the first Tuesday of June, 1889. When the members of the Society who were able to reach Pittsburg met on that day, they found that, owing to the terrible disaster at Johnstown, a large number of the delegates could not be present, and they adjourned to meet on the first Tuesday of September. Now, the Committee of Arrangements have assumed the responsibility of dispensing with the meeting of the Society altogether this year.

The question arises, Has that Committee of Arrangements, appointed for a special purpose, the right to assume the authority of the whole Society, and say no meeting shall be held in this year? For one, I think that they can only exercise the authority delegated to them, and cannot assume rights which the Society alone at a regular meeting can determine.

The principle always recognized is that no committee have the right to go beyond the duties specially assigned to them by the society which appointed them, and in this case the determination of that Committee that the Society shall not meet in this year is an assumption of power entirely beyond that delegated to them in their appointment as the Committee to make arrangements for the regular meeting of the Society in Pittsburg, and that only. Besides, they have fixed a day on which it will be impossible for several members who desire to attend to be present.

JOHN CURWEN.

WARREN, PA., July 29, 1889.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JULY 16 TO JULY 29, 1889.

By direction of the Secretary of War, WILLIAM H. GARDNER, *Major and Surgeon*, is detailed to attend the encampment of the National Guard of the District of Columbia, at Fort Washington, Maryland, from July 22 to July 29, 1889, for the purpose of giving instructions to the Medical Officers and Hospital Corps in their respective duties.—Par. 1, *S. O. 164, A. G. O.*, July 18, 1889.

By direction of the Secretary of War, the extension of the leave of absence on surgeon's certificate of disability, granted H. G. BUNTON, *Captain and Assistant Surgeon*, in S. O. 22, January 26, 1889, from this office, is further extended two months on account of sickness.—Par. 1, *S. O. 162, A. G. O.*, July 16, 1889.

By direction of the Secretary of War, WILLIAM R. STEINMETZ, *Captain and Assistant Surgeon*, now at Baltimore, Maryland, on leave of absence on account of disability, will report in person to the commanding officer of the Watertown Arsenal, Massachusetts, for duty at that station, relieving James C. McKee, Lieutenant-Colonel and Surgeon.—Par. 3, *S. O. 166, A. G. O.*, July 20, 1889.

MCKEE, JAMES C., *Lieutenant-Colonel and Surgeon.*—On being relieved at the Watertown Arsenal, will repair to Philadelphia, Pa., and assume the duties of Attending Surgeon and Examiner of Recruits in that city.—Par. 3, *S. O. 166, A. G. O.*, July 20, 1889.

ROBINSON, SAMUEL Q., *Captain and Assistant Surgeon* (Fort Hamilton, New York Harbor).—Is hereby granted leave of absence for two weeks.—Par. 11, *S. O. 165, Headquarters Division of the Atlantic*, July 22, 1889.

BALL, R. R., *First Lieutenant and Assistant Surgeon.*—Leave of absence granted in S. O. 87, Department of the Missouri, July 9th, is extended five days.—Par. 1, *S. O. 167, A. G. O.*, July 22, 1889.

BALL, R. R., *First Lieutenant and Assistant Surgeon*—The extension of leave of absence granted in S. O. 167, July 22, 1889, from this office, is further extended ten days.—Par. 23, *S. O. 169, A. G. O., Washington*, July 24, 1889.

By direction of the President, the State of Arkansas, embracing Little Rock Barracks, is transferred to the Department of the Missouri.—*General Orders No. 66, Headquarters of the Army, A. G. O*, July 19, 1889.

PROMOTION.

EWING, CHARLES B., *Assistant Surgeon.*—To be Assistant Surgeon, with the rank of Captain, July 5, 1889, after five years' service, in accordance with the Act of June 23, 1874.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL ARTICLES.

HYDRONEPHROSIS AND RENAL ATROPHY; ESPECIALLY AS RESULTING FROM FUNCTIONAL DISTURBANCES OF MICTURITION.

BY ROBERT T. EDES, M.D.,

OF WASHINGTON, D. C.,

FORMERLY PROFESSOR OF MATERIA MEDICA AND JACKSON PROFESSOR OF CLINICAL MEDICINE IN HARVARD UNIVERSITY.

HYDRONEPHROSIS is a dilatation of the pelvis and calyces of the kidney from retention of the secretion. It may vary from the slightest stretching of the pelvis beyond its normal dimensions, with perhaps a slight flattening of the papillæ, up through all the stages of gradual distention of the cavity and atrophy of the renal substance, until the kidney becomes a mere shell of fibrous tissue, to which are attached a few remnants of true renal parenchyma retaining somewhat of their structure and function. This condition may affect both of the kidneys, or one of them, or in some cases only a part of one.

It is so nearly always the result of a demonstrable anatomical obstruction in the normal flow of the urine that, in the few cases in which the exact seat and nature of the obstruction cannot be discovered, it is fair to conclude that the exception does not indicate an independent pathology, but simply that hindrances may exist which are not obvious to the sound or on the dissecting table. This remark applies quite as fully to congenital as to acquired hydronephrosis.

The object of my paper is to suggest that in some of these exceptional cases the search, if prosecuted during life physiologically and clinically, will reveal causative conditions not evident upon the post-mortem table, but, notwithstanding, really sufficient for the effect produced.

The points at which obstructions may occur are many; and according to their positions will be the amount and character of the changes existing above them; not only the dilatation, which is the subject of the present paper, but the inflammatory and degenerative alterations in addition. These lesions have been carefully studied and described, and I will take but a few moments in a brief recapitulation.

The ureters may be occluded by a calculus at any point from their exit from the pelvis to their entry into the bladder.

Wounds or blows on the back may cause compression of the ureters by means of hemorrhagic or inflammatory effusions.

An obstacle may also exist anywhere in their length in the form of a valve or fold, constituted either by the mucous membrane or by the whole thickness of the tube. Such a valve, although retaining the secretion most of the time, may be pervious under some states of distention or position; and in this way are formed the so-called intermitting hydronephroses. Folds or kinks existing in the ureters have long been recognized as obstructions, but it is possible in some cases that these may be, in part at least, secondary, inasmuch as when a hydronephrosis occurs from other causes which may be temporary, the ureter is not only dilated but also lengthened, and is obliged to form a fold in order to accommodate itself to the surrounding parts. They are frequently, however, of such form and in such numbers that no such explanation is admissible.

The ureters may be congenitally impervious through the whole or in any part of their course. (*Trans. Path. Soc. London*, xv.; *Bull. Soc. Anat. de Paris*, 1867, xxxi. 11, 305.) They may have no opening into the bladder or even attachment to it. (*Med. Times and Gaz.*, 1876, i. 546.) In some such cases there is an attachment to the rectum but without an opening into it. (Gerster: *N. Y. Med. Journal*, 1878, xxviii. 511.) When arrested or irregular development of this kind occurs in the ureters, it is not uncommon, in fact usual, to find associated with it other deformities, frequently of the intestinal canal, but often of entirely separate regions; as, for instance, the hands and feet, showing a tendency in this direction more than local. There have been instances where a woman has borne several hydronephrotic children in succession.

Whenever the obstruction exists long enough there will be a dilatation of the parts above, not necessarily everywhere equal, since the ureters differ in density and in the amount of outside support they receive at different parts of their course. It is not unusual to find in the course of a ureter which is elsewhere considerably dilated, points at which it retains its normal calibre. One of these points is likely to be found just where the pelvis of the kidney joins or becomes the ureter.

Compression of the ureters may be caused by bands of adhesions and in a few cases by a branch of the renal artery passing across them.

Among the more common external obstacles are to be found pelvic tumors and in particular cancer of the uterus. Displacement of the uterus, and in particular prolapse, can have this effect by twisting and dragging on the ureters.

The brim of the true pelvis, where the ureter makes a somewhat abrupt turn, and is especially liable to compression in passing from the abdominal cavity down behind the bladder, may cause an obstruction to the flow of urine, as will be shown by the difference of calibre, the tubes being dilated above and normal below. (*Medical Record*, 1887, xxxii. 734.)

As we come lower, omitting the bladder itself, which will be more fully discussed later, we may find the obstacles where the urethra leaves the bladder. This may be absolutely impervious, there being no orifice whatever, its proper position being indicated by a papilla (Billard: *Maladies des Nouveau nés;* Lehmann: *Nederland. Weekblad.*, 1853, No. 12); or there may be an adhesion of the sides of the urethra in this region too strong to be overcome by the pressure of urine, but yet easily broken up by an instrument passed in the usual way, which relieves the distended bladder and removes its cause, or cutting may be necessary. (Lamotte: *Traite des Accouchements;* Smellie's *Midwifery.*) In other cases nearly the whole urethra may be obliterated or wanting (Lehmann, loc. cit.). It may, like the ureters, be obstructed by a valve of mucous membrane. (*Bull. Soc. Anat. de Paris*, 1869, p. 130.)

In the adult the hypertrophied prostate is a not infrequent obstacle, and gives rise to an incipient or moderate bilateral hydronephrosis, as in the specimen just shown by me,[1] and in one by Dr. Prentiss (*Maryland Medical Journal*, April, 1883), and in many others too numerous to quote.

The function of the kidneys may not be seriously disturbed for a long while.

If a cystitis is added, as it is likely to be, we may then have, not a simple dilatation of the passages, but, from the fact that it is an inflammatory urine which is backed up into the kidneys, a pyo- instead of a hydro-nephrosis.

This list is to be extended by the mention of strictures of the urethra, of which there are several specimens in the Army Medical Museum, and of papillomata in the neck of the bladder.

Finally, the prepuce may present an efficient obstacle in the form of a phimosis, although the irritation of an adherent foreskin may lead to hydronephrosis by another chain of causation, as will be seen later on.

Many of the conditions mentioned can, of course, exist only in the fœtus or the newborn. Where a sufficient amount of depuration of the blood can be carried on by the circulation of the mother without reference to the activity of the fœtal organs, one or both kidneys may, even if entirely obstructed, continue to grow into the enormous tumors of this kind sometimes met with. A certain amount of time is requisite for the development of an extreme degree of hydronephrosis. It is a process of growth and not simply one of distention, and since after separation from the mother an absolutely complete occlusion of both ureters in the child must lead to death by uræmia before the dilatation can reach its extremest limits, we meet with the most striking examples of double hydronephrosis in connection with impervious urinary passages only in the fœtus or the newly born. The abdominal swelling in some of these cases of congenital hydronephrosis may be so great as to constitute a serious hindrance to delivery or, on the other hand, the pressure during delivery may be so great as to force a passage of the urine in spite of the resistance and empty the sac.

In adults an absolutely impermeable obstruction may exist upon one side and a slight or moderate hydronephrosis be formed in consequence, but, when the dilatation is bilateral or when it is extreme on one side, it must have been the result of an obstacle sufficient to increase the pressure under which the urine was secreted during a long time, but not sufficient entirely to stop it at once. The stoppage may finally become an absolute one, but cannot have been so from the beginning.

It is a curious fact that the amount of urine passed against a certain degree of back-pressure instead of being diminished, as we should naturally expect from a knowledge of the physical laws governing this secretion, is increased. The back-pressure, when not too great, seems to act as a stimulant to the secreting structure. If, however, it gets beyond this point, the secretion obeys the ordinary law of physics and takes place more slowly.

After the consideration of these and all similar causes for hydronephrosis, we are likely to meet with cases which are not to be explained thereby. My former instructor, Prof. J. B. S. Jackson, went so far as to say that in a large proportion of cases, so far as he had seen, no cause whatever could be assigned. We may accept, as expressing the general conclusion in the matter, the words of Roberts, who says, "There are cases which must at present be regarded as mechanically inexplicable." I propose now to examine a case or two of my own with reference to the causation and compare them with a few observations I have been able to find in medical literature.

Case I.—A boy, aged five, was seen by me in December, 1882, with my friend Dr. Gilbert, of Dorchester. He looked rather less robust than his younger brother and sister. He had always been

[1] To the Medical Society of the District of Columbia.

in the habit of wetting his bed and clothes. Recently his habits had improved, although he still passed a small amount of urine in his clothes. He did not, however, entirely empty his bladder in this way, as his mother said he could always pass water whenever they tried him. There was no difficulty in micturition. He passed a full stream. The daily quantity was considerably increased and was of low specific gravity with a small amount of albumin and a slight sediment of small cells, but no casts. Two years later the urine was still lighter and it contained albumin, but no casts. A short time before his death he had several attacks of retention of urine. He had headache for a month or two, and his death was immediately preceded by convulsions.

At the *autopsy* the body was found emaciated. The heart was hypertrophied, especially the left ventricle. The right kidney was represented by the dilated pelvis and a small nodule of secreting structure at one end and a few thin pieces elsewhere; right ureter dilated. The left kidney somewhat atrophied, mottled with yellow, lobulated, capsule adherent, pelvis and ureter slightly dilated, but much less than right. Bladder large, the walls more trabeculated than would be expected in a child of his age. No obstruction anywhere in ureters found. Free passage of water into bladder and free passage of sound in either direction. Urethra free to sound in either direction.

The next case lacks the confirmatory evidence of a post-mortem but presents what is better, the result of treatment directed to the relief of the causative condition.

Case II.—A rather delicate girl, aged three, was seen by me in consultation with Dr. Rice, of Grafton, Mass., in January, 1886. She had had a convulsion in the previous July and some feverish attacks since. She had passed urine in large quantity and with some effort for some months, and these were all the obvious symptoms. The urine was of low specific gravity and contained a large trace of albumin with pus, blood, epithelium from the neck of the bladder, renal epithelium, and some casts. A previous examination had discovered some epithelium from the pelvis of the kidneys. She was placed on the benzoate of lithium, with which her general condition improved, and she went through the night without passing water, but the albumin, pus, and casts remained, and were noted on several examinations up to March 7th. On the 8th the bladder and urethra were examined under ether. She passed a full stream of urine and a large bougie entered the bladder without difficulty. A probe detected a little roughness (trabeculation?) at times, but nothing more. On the 26th of March her mother wrote to me that she had seemed much better, appetite very much improved, and since the examination *decided decrease in the effort to pass water.*

The next examination of urine, of which I have a record, shows there was a deposit of pus and some albumin present, but no casts were found after a somewhat prolonged search and only a few large cells.

The urine of June the 14th was opalescent and deposited only a flocculent stratum of pus. One hyaline cast of medium size was found after searching a number of drops. On the 15th a large taper-pointed catheter was introduced into the urethra for puposes of dilatation, and the urine drawn contained neither pus nor casts, and only a small amount of albumin. On the 23d there were a few scattered leucocytes and no casts. Some time in the winter of 1887–8 the urine contained a trace of albumin, but in July, 1888, the attending physician writes that "It is free from albumsn and the patient is the picture of health."

If we take into consideration cases where hydronephrosis coexists with thickened bladder and a severe chronic cystitis, and where the dilatation is fairly referable to the increased frequency of micturition and the spasmodic contraction of the bladder, we can find a considerable number.

Case III.—In a case under my own observation (seen with my friend, the late Dr. Arnold, of Roxbury, in its last stages), a boy had attacks of dysuria from irritability of the neck of the bladder, and probably cystitis, from the age of six to nine. For some time before his death the urine was pale, scanty, purulent, and ammoniacal. He died with uræmic symptoms. The bladder was thickened and the ureters dilated. The right kidney was represented by a nodule the size of a pea on the outside of the membranous bag. There remained of the left kidney one round mass at the lower end three-quarters of an inch in diameter, and two or three other smaller ones.

I think we have in the first two of these cases a complete and a fortunately incomplete instance of the class recognized by all writers on this subject as "mechanically inexplicable"; inexplicable—that is, if we regard only the conditions found after death or by surgical examination, since we find a hydronephrosis with indications of increased work on the part of the bladder, but the passages everywhere freely permeable to instruments in either direction; *not* altogether inexplicable, if we regard the action of the bladder and the function of micturition.

The amount of back-pressure in the kidneys required to produce a complete compression of the secretion is estimated at about one and six-tenths inches of mercury, while less than half an inch will greatly impair it.[1] Since, then, in most cases of hydronephrosis the secretion is not checked, but the contrary, we may safely say that a very small amount of back-pressure in the bladder, if constant or frequently repeated, is sufficient, after a time, to produce slighter grades of hydronephrosis with consequent destruction of kidney substance.

Normally, of course, there is little pressure in the bladder most of the time. Once emptied, it fills

[1] Wundt: Physiologie des Menschen, p. 434. Quoted by James: Physiological and Clinical Studies, Edinburgh, 1888.

again with urine coming down the ureters, partly perhaps by hydraulic pressure, but largely by the peristaltic movements analogous to those by which the intestinal contents are propelled.

To this there is little or no resistance on the part of the bladder until a certain degree of distention is reached, varying, not only according to its total capacity, but according to its irritability, when it is emptied by a contraction of one set of muscles and relaxation of their opponents.

It is stated that the detrusor urinæ is able to overcome the resistance of the sphincter vesicæ, but it comes within the personal experience of everyone who has been obliged by circumstances to delay the evacuation of the bladder after it has become overfull, that something more than overcoming a passive resistance is necessary in the act of micturition. There must be a simultaneous and harmonious relaxation of the sphincter as well as stimulation of the detrusor. In this respect micturition may be said to resemble vomiting, where efforts of the abdominal muscles are unable to evacuate the stomach until the cardiac orifice relaxes.

The function of the urinary bladder in receiving and discharging the urine at more or less regular intervals is not a purely passive one. It should be a pump as well as a reservoir. Its proper action in this way depends on a proper relationship between the forces that propel and those that restrain its contents, and when these forces are so disordered that it fails to perform its function, or performs it insufficiently, then more work is thrown upon the other propelling forces. These are: first, the pressure under which the urine is secreted, which, as we have seen, is but slight, since half an inch of mercury pressure will materially impair it; and, secondly, the peristaltic movements of the ureters.

During the normal act of micturition no urine can, of course, enter the bladder from the ureters, but since the emptying of the bladder occupies so short a time no harm is done. The amount of urine which accumulates in the ureters during this interval is too small to distend them beyond the proper limits. If, however, the contractions be very frequent and long continued there will be enough accumulation of urine in the ureters to cause their dilatation, and, subsequently, that of the kidneys This dilatation, by weakening the walls of the ureters, will naturally tend to increase rather than decrease. Such frequent contractions result, as we well know, from various sources of irritation in the urinary tract, but especially from inflammation of the bladder itself, or of the urethra.

Suppose, now, on the other hand, the detrusor to be weakened relatively to the sphincter, or, what amounts to the same thing, the resistance of the sphincter to be increased, we may have a considerable accumulation of urine taking place against the constant elastic pressure of the bladder which is not, however, sufficient to empty it, and allow the flow from the ureters to go on again without resistance. We then have the condition of incontinence from retention—*i. e.*, a bladder full to overflowing, so often seen in the old, usually in connection with enlarged prostate, but not common in the young. The kidneys and ureters are thus working against a pressure, never very great perhaps, but always above the normal, exactly the condition to produce a gradual distention. If the voluntary muscles of the abdomen are called upon to assist the contractions of the bladder, the matter is made worse rather than better, for they cannot exercise so equal a pressure in every direction as the constrictors of the bladder itself, and the entrance to the ureters is not guarded, under the circumstances, as in the normal condition, by the contraction of the fibres immediately surrounding them. Urine may thus be forced upward as well as downward. The absence of the valvular condition of the entrance of the ureters into the bladder is expressly noted in two of the subsequent cases of paralysis of the bladder.

It will, of course, be understood that the amount of pressure required to produce dilatation in the course of weeks or months is an entirely different amount from that which would be necessary suddenly to dilate the organs to the size they may attain even in the more moderate cases of hydronephrosis. In fact, it would probably be impossible to arrive at this state of things by any rapid process.

Hydronephrosis, then, may take its rise in two distinct forms of faulty innervation, paralysis and spasm. This origin is not fully recognized in medical literature, but a few cases may be quoted in support of my view.

Augè (*Thèse de Montpellier*, 1878) reports a case of hydronephrosis from paralysis of the bladder, of which, however, the clinical details are too scanty to make it of much value for our purpose. The bladder was greatly dilated, it was thin, and the mucous membrane injected and punctated. The ureters were much dilated and the inferior orifices opened. The pelves of the kidneys were dilated and the tissues progressing toward atrophy.

The following somewhat resembles the first of mine. Bernard (*Journ. Sc. Méd.*, Lille, 1881, p. 546) describes the case of a child, aged thirteen, who had incontinence of urine, wetting the bed, and passing water into his clothes during the day; he could pass water whenever he pleased, with some difficulty, the jet being short, and he being obliged to contract energetically the abdominal muscles. When sounded, the bladder was found to contain a considerable quantity of urine, but there was no obstacle to catheterism, and no calculus. The mus-

culi recti abdominis were hypertrophied. There was a large quantity (three litres) of urine passed, which deposited muco-pus. After death the bladder was found to contain urine, pus, and blood, and was as large as the fist. Ureters dilated. Of the left kidney the structure was entirely gone; in the right the changes were less advanced, but there were abscesses. The ureters were without the usual valvular opening into the bladder, being without any intra-parietal portion. There was thickening of the walls of the bladder, and slight cystitis, but the urethra was normal.

James (*op. cit.*, p. 42) reports the following: A child had, at three, phimosis as the result of an injury. After this had been "pricked by a doctor," the swelling got better, and he seemed nothing the worse. He had then no incontinence. The incontinence began at the age of four. After this a feverish attack which weakened him, and, on admission to the infirmary at the age of eight, he looked thin and weakly. The prepuce was contracted and almost completely adherent to the glans. No pain, but great incontinence. There was increased frequency of micturition, often three or four times in an hour. Only a few drops of urine were passed at a time, and the bladder was never distended. The quantity of urine was probably increased, and it was pale, with a small amount of pus and renal cells. Circumcision gave temporary relief, but he finally died comatose.

The bladder was somewhat contracted, and its walls thickened.

There was no cystitis, but great roughness, owing to the hypertrophied muscular fasciculi and diverticula. The cavity of the bladder, when distended, was smaller than natural, and the walls about a quarter of an inch thick. There was no stricture in the urethra, and the openings of the ureters through the bladder-wall were normally patent. Both ureters were greatly dilated in their entire length; both kidneys were hydronephrotic.

The author remarks that this is one of three similar cases, in the other two of which the cause of the urinary irritation was the condition of the prepuce. He also mentioned other cases where incontinence, associated with an abnormally light urine, was relieved by circumcision.

The following references belong to cases which may have had something of this character, but in which the clinical details are not sufficient to enable us to classify them with certainty.

A case read by Dr. Acker to the Medical Society of the District of Columbia, on February 13, 1889: A child of five had phimosis, but was said always to pass a good stream. The urine was said to be normal, but latterly profuse. Death from tuberculosis. The bladder was thickened, and the ureters and pelves of the kidney slightly dilated.

Webster (*U. S. Med. and Surg. Journal*, June, 1835).

Ramsbotham (*Proc. Path. Soc. London*, 1848–49, p. 75).

Little (*Path. Trans.*, 1861–62).

Broadbent (*Path. Trans.*, xvi. p. 165). The reporter of this last case thinks there may have been a valve in the urethra because one was found in the ureter.

There is a point in the first one of my cases to which I should like to call attention, although not intimately connected with the subject of the paper —that is, the occurrence of hypertrophy of the heart in connection with a purely local disease of the kidneys. This has been noted in other cases, some of which I have come across in consulting the literature of the subject without this special object in view. It has occurred in cases of traumatic origin.

These facts are not in harmony with the theories largely held in regard to the connection of cardiac and renal disease, nor indeed with that which I have myself advocated, to the effect that this connection consists in a common dependence on a primary condition of the whole arterial system, at first functional, and afterward structural. They seem to show that, sometimes at least, the kidney lesion may be directly causative of the cardiac change, and without any intervention of arterial degeneration.

The following report cases of the kind:

Footner (*British Med. Journal*, 1878, xi. 57).

Weill (*Mém. et Comptes Rendus de Soc. de Méd. de Lyon*, xxiii. Pt. 2).

Soller (*Lyon Méd.*, vol. xxxv. p. 233).

Is it not possible that some cases of interstitial nephritis in the young, even when they are accompanied by hypertrophy of the heart and by the other symptoms usually found in older persons, may originate in some local trouble, and not be so closely connected with a constitutional affection as those with which we are more familiar in persons in middle life? Certainly the causes to which we attribute, so far as we can, chronic interstitial nephritis are less operative in the young.

It seems to me not unreasonable to suppose that even that quite slight obstruction to the flow of urine may, by the mechanism described above, and without producing more symptoms than can easily be overlooked, set up an amount of renal irritation that will in time run into chronic interstitial nephritis; and that the back-pressure may be so slight as to fail to dilate the ureters and exert itself solely on the renal substance. This, I admit, is pushing my doctrine to its extreme limits and beyond the bounds of demonstration, but I offer the suggestion for what it is worth.

THE INFLUENCE OF CLIMATE AND SEASON UPON THE MANIFESTATION OF NORMAL AND ABNORMAL NERVOUS ACTIVITY.[1]

BY W. B. PLATT, M.D.,
OF BALTIMORE, MD.

WHEN we reflect that all intelligent—that is, co-ordinated—muscular movement, is dependent upon nervous impulses, and that without muscle contraction we have no possible way of manifesting life, much less intelligence, it is evident that the nervous centres should be placed under the most favorable influences to secure the greatest benefit to the individual and to society. The conditions which affect and direct action, are climate, race, and environment. We are, moreover, all aware how large a share climate is believed to have in the production of both race and environment. The individual who is able to rise above the most unfavorable conditions involving all three of these, and excel men of prominence who have attained their position under circumstances the most favorable, may be left out of our calculation. He so nearly escapes the laws affecting large bodies of his fellow-men as to entitle him to be called a genius.

We place *climate* first of all, since it is that which, acting through generations, is believed to aid so largely in establishing race, which helps to alter environment—that is to say, institutions—and which may be in part itself determined by the physical characteristics of the region affected.

We may measure normal nervous activity by the quantity or quality of its products, or, better, by both. To have something tangible we must take the products of a given State and compare them with those of other nations or states in amount and kind. There is hardly a country in the world where to-day such a comparison is fair unless it be between different portions of our own, making due allowance for such race differences as exist.

This great fact of race difference is constantly held before us as the cause of difference in production. The Caucasian races are more easily compared than others because they alone show a tendency to produce more than they can consume, to an advancement in science, art, inventions, and to constant accretions of capital.

The complexity of the subject is enormous. To single out one factor, such as climate, to measure and weigh its force apart from concurrent forces, would require a volume. The concrete fact, however, remains, that the world over, in cool not cold climates, at moderate elevations above the sea (within 1000 feet) we find in its greatest perfection, that constantly acting, intelligent nervous force which produces greater results in all fields than in warmer or colder regions.

That climate and season have a powerful influence for good and evil upon the organs of respiration and circulation has long been recognized, but that it has also an influence in certain definite directions upon the nervous system has been pointed out by only a few observers and recently, and has been almost lost sight of in the labors of this and kindred associations. The reason is not far to seek, since the relation of cause and effect is not as apparent as in the case of the thoracic viscera, and the difficulty of isolating their effect is greater in the case of neuroses. Some of the visible effects upon the nervous activity of individuals or nations, of climate and season, are only visible after generations or years, others may be noticed in weeks or months.

We must limit our inquiry to a few distinct types of nervous derangement characterized by striking evident phenomena, where we expect to show that a definite causal relation exists between climate and season and such nervous morbid action as is expressed in chorea, acute polio-myelitis of children, suicidal tendency, and neurasthenia. Here, also, might be included some of the peripheral neuralgias.

CHOREA.—In spite of the experiments of Brown-Séquard, who proved that in dogs the choreiform phenomena were probably due to some lesion in the spinal cord, later investigations point to the brain itself as the seat of the disease in man. Without going into the anatomical appearances sometimes found, how fright can be a direct cause of chorea, nor what the real relation of endocarditis to chorea is, we will look into the connection between climate and season to the disease in question. Weir Mitchell's and Gerhard's studies are the only ones where anything more than mention has been made of the subject. They showed conclusively, from a study of 170 cases of separate attacks of chorea, that it is far more common in cool than in warmer climates. In Baltimore, where more than 10,000 cases of all kinds have come under my observation at the Garrett Free Dispensary, I have not had 25 cases of chorea. Of this small number not one was black.

Of Dr. Mitchell's cases the number of attacks increased by an enormous bound from February to March, when it reached its maximum of 35, falling to 15 in April, rising again to about 18 in May, and continuing thus until July, when it slowly fell until December. These all occurred in the latitude of Philadelphia, and extended over a period of four years. The attacks appeared to have no relation to the rise or fall of the barometer, to the rain-fall, or to the thermometer, excepting as the relative rise is greater in the spring than in other months. The number of attacks did, however, show a remarkable coincidence with the number of storm-centres passing

[1] Read before the American Climatological Association, June 29, 1889.

within 750 miles of Philadelphia. The observations on this point extended over a period of two years, and the curves of the number of storm-centres and that of the attacks of chorea are almost parallel until the month of September.

As we have already noted that the chorea curve had no relation to that of temperature or atmospheric pressure at the place of occurrence of attacks, we must conclude that some other causes than these are in operation to excite the attacks in question. We might define chorea as a disease of childhood and youth, characterized by chronic, intermittent, muscular twitchings, without loss of consciousness, often accompanied by endocarditis, and caused by an irritation of the cerebral motor ganglia. It is a disease of cities rather than of the country, of whites rather than of blacks, of females rather than of males, of the spring months, and of cool climates.

Dr. J. K. Mitchell informs me that he investigated the relation of attacks of *apoplexy* to season at one time, expecting confidently to find some relation. He found, however, nothing in the least to indicate that any connection existed between them.

In regard to *acute polio-myelitis* of children, or *infantile paralysis*, Wharton Sinkler, of Philadelphia, found it immensely more frequent in that city in the hot than in the cooler months. The curve of the number of cases rises rapidly from May to the first part of August, falling abruptly to the first week in September, running then in an even course until November, when it fell to its lowest point in December. While its curvè does not run exactly parallel to that of the temperature, the main course is very near it. Just as in cholera infantum and the diarrhœal diseases of children where the mortality and the degree of heat are closely related.

Concerning *suicide*, we see at a glance that race has much to do with its frequency. Those who believe that race and the peculiarities which cause the difference in races, are due to climate, will find support in the fact that negroes, for instance, very seldom commit suicide; carrying into cooler climates a peculiarity acquired by residence for many generations in a hot climate.

Savages have such an immunity from suicidal impulse, that we may in general define it as one of the diseases incident to civilization, one of the throes of the human race, painfully passing through stages of evolution which bring with them burdens too heavy to be borne.

The influence of climate and season upon suicide is most remarkable. S. A. Hill, in his *Statistics of an Indian Province*, shows that suicides, violent deaths, and wounds, are at a minimum in the colder months, increase in frequency during the hot and dry season, and remain high during the rainy season. The irritability of temper caused by prolonged heat and moisture is suggested by him as a reason. The same writer says that December is the month of most frequent conception.

The literature of suicide is enormous, as anyone who looks up the subject for any point connected with it will see. Dr. Pilgrim, in the July number of the *Popular Science Monthly*, says, "Suicides are most frequent in April, May and June. July and September have a good proportion, while they are fewest in October and November." M. Guerry is quoted as proving that some days of the month and week and some hours of the day are more often chosen than others for suicide. He found the greater number occurred during the first ten days of the month, due probably to the fact that wages were then received and spent more often than later in the month; their receipt being followed by dissipation, reaction, and self-destruction. There were likewise more cases occurring from Monday to Thursday. A French writer on the subject, Brierre de Boismont, shows that of 1993 suicides in Paris, most of them occurred between 6 A. M. and noon; thereafter regularly declining in frequency until just before sunrise. They are also said to be especially frequent shortly before breakfast-time, and very seldom just after dinner.

There are also epidemics of suicide due to social causes, which might as well be called "social nerve-storms." In Versailles, for instance, there were in one year 1300 suicides. The statistics of lunatic asylums show at certain times a much larger number of admissions of patients with suicidal tendencies than at others. Dr. Pilgrim quotes from the report of the State Lunatic Asylum of New York, showing that in July, 1850, there were admitted 28 suicidal patients. In that month, of 44 patients altogether admitted, 19 of them were suicidal. From the 12th to the 22d of the month there were 14 attempts to commit suicide among 8 persons.

To estimate correctly the influence of any one element, such as climate or season, we must see what other factors there are and eliminate these if possible. A recent writer, in an article entitled "Baits for Suicide," deplores the influence of a certain class of literature upon those likely liable to suicidal impulses, and dwells particularly upon two well-known works of fiction, *Lady Audley's Secret*, and *Aurora Floyd*.

One factor is age. Forbes Winslow (*Journal Psych. Medic.*) shows that the tendency to suicide first appears at from 10 to 15 years of age, is most frequent among males from 55 to 65, and among females from 65 to 75, in Great Britain. An imperfect education appears to be worse in its suicidal tendency than ignorance. Whatever we may think of the proverb that "Ignorance is the mother of devotion," we cannot call suicide a child of hers,

since suicide is absolutely less prevalent among the illiterate than among those who are more or less educated. Radcliffe, in "English Suicide Fields," etc. (*Journal Psych. Medic.*, vol. ii.) holds that nowhere is this relation of suicide to ignorance more manifest than in Great Britain; being more prevalent in the more highly educated districts. Farr attributes this with justice, not to the advancement of science and knowledge, but to the development of small trades, such as that of tailoring, shoemaking, and the like.

Sex is another important factor. In New York, in 1883, there were 161 suicides; of these, there were 134 males and but 27 females. Nationality plays a curious part, for of these, 70 were among the Germans, who, as far as worldly prosperity is concerned, are more prosperous than the other great immigrant class, the Irish. Religion and the lack of it have an important bearing. Except among the absolutely insane, a belief in a future life of reward or punishment, exerts a decided restraining influence on the tendency to suicide. Without this, suicide is a logical and welcome means of escape from hopeless despair, misery, or disgrace.

Well-marked insanity is another and with us the most important of influences in producing suicide, although, as we shall see, this in turn is greatly influenced by climate. In England, in 1865, there were 1600 suicides; most of these attributed to insanity. How many more there might have been may be seen from the fact, that during this year there were in insane asylums 6096 patients with suicidal tendencies. The English believe that most of their suicides are to be found among the insane, and fewer due to despair, remorse, and sense of disgrace, which act as powerful motives on the Continent. Aside from well-marked insanity, in the popular acceptation of the term, the passions are the most important direct cause of suicide. Imitation is a most important exciting element in suicide. The mere mention of some remarkable or striking mode of self-destruction, is sure to be followed by a number of similar cases over a large area, and this area would, we believe, be found to correspond pretty closely to the region reached by the newspaper account of the case in question. It is well known that melancholic insane are the most suicidal in their tendency. In four years there were 2106 patients in the Utica Asylum for the Insane. There were 512 cases of melancholia, and of these there were 130 suicidal patients, or 35 per cent. This is about the usual per cent. There were but 50 cases among the remaining inmates.

Among suicides from disgrace, military sentiment, etc., may be mentioned the case of the son of the famous Marshal Wrangel, who, finding that his son, an officer in the army, had utterly lost caste in consequence of his misdeeds, paid all his debts, and said "Now there is but one thing further for you to do, you will find what you need in the next room," referring to a loaded pistol which he had laid upon the table, and the son, truer to military tradition at last than at the first, took the hint without delay. The instance of Rudolph of Austria is too well known to require further comment as a result of passion and mistaken sentiment. When, however, we take large areas among various nations and find that suicide is far more common in cool than in warmer climates, we are compelled to admit that climate is one great causal factor. Explain it as we will, call its influence direct or indirect, there are far more suicides in northern than in southern countries. Dr. Grissom, of North Carolina, in whose asylum there are on an average 200 insane, has never had a suicide, and we think no one would venture to believe that institutions for the insane have better management or attendance in the South than in the North. He (Dr. Grissom) is said to have attributed this remarkable immunity to the restraint system. The statistics of the Maryland Hospital for the Insane, near Baltimore, whose able and intelligent Superintendent, Dr. Gundry, has long since abolished restraint, and where there are at present 430 inmates, with an average of from 350 to 400, for five years, has had but one suicide in ten years. It may here be said in respect to nationality that negroes, in spite of their hopelessly inferior social position, and who seem condemned to servitude, if not hard labor all their days, seldom destroy themselves.

It is the testimony of numerous observers—Quetelet, Tissot, Winslow-Hawkins, Gundry—French, English and American, that suicide is more common north than south, and more common in warm than in the colder months. Of the warmer months, the months of April, May, and June certainly predispose to or excite to suicide.

The fact that more cases of the so-called *neurasthenia* occur in the spring months, than at any other time of the year, must be evident to every general practitioner or specialist who has to do with the class in which these cases arise. Those students who habitually omit to take arm exercise, furnish a large contingent. I have seldom seen a case of neurasthenia in a man who kept reasonable hours, avoided excess of stimulants, narcotics, or sexual indulgence, and who took some form of regular arm exercise.

Such a man will become so fatigued when he enters the confines of mental overwork as to be incapable of it. We find those who are ill-balanced morally, by far the most sensitive to influences that the normal man easily withstands.

The Elmira Reformatory, of New York, with its

1000 inmates between the ages of eighteen and thirty—all criminals—is a fruitful field of observation of nervous instability, and I cannot improve upon the remarks of Dr. H. D. Wey, who has kindly replied to my inquiries as follows:

"It is a well-known fact that 'nerve storms' or ascending nerve currents are encountered every spring. There is no fixed time for their appearance, although they usually manifest themselves either in February or March. This year they appeared in the latter part of January. Whether there is any connection between their early manifestation and the unusually forward spring, I cannot positively say; but reasoning inferentially, it would seem as if there was.

"The old saying runs, that 'In the spring of the year the necks of the bucks begin to swell.' It is very seldom that our annual attack of 'cussedness' comes on as late as the month of April. It seems to occur coincident with the renewal of life in the vegetable kingdom and has never been noted in any degree during the decline of vegetation in the fall. It manifests itself in irascibility. and a disposition to break in upon and infringe the rules of discipline. The animal nature seems to come to the front. Two men may be working quietly side by side, when without any provocation, one man will fell the other to the ground, possibly inflicting serious injury.

"Assaults upon officers are more common than at any other season. In 1880, there were two suicides and two homicides, all within a period of two months. There seemed to be no other reason for the tragedies than that they were the outcome of the nerve tension incident to the season of spring. At this time it is necessary to observe unusual vigilance. None recognize this fact better than old officers. School-work seems to drag, and it calls for unusual effort for the men to apply themselves to their mental tasks. Shop-task work is performed with greater difficulty and frauds in its execution are constantly cropping out. Such, in brief, are the phenomena noted in general. In the individual can be studied the conflict going on between two natures; a Dr.-Jekyll-and-Mr.-Hyde contest, in miniature.

"In everyday life, *Monday* morning is the most troublesome period of the *week*. The quietude of Sunday, the absence of customary duties, and the communing of each man with himself seem to bring to the surface on the following day all that has been held back and repressed during the week. In view of this it is sought to impose upon each man as much Sunday occupation as is consistent with the day, religious services for all denominations, Protestant, Romish, and Hebrew, examinations in English literature for the most advanced, popular talks and lectures by the best talent we can obtain. All that is emotional or that appeals simply to sentimentality is avoided, and for this we have been criticised as Godless.

"Regarding insanity, I cannot say I have noted its presence to a greater degree in the spring than at any other season of the year. When it does occur in the spring it would seem as if it must be looked upon as the giving away of a mind that is non-resistive, and unable to participate in the strain to which the nervous system is being subjected. I have noted that with a rising barometer the men are buoyant and elastic, and perform their tasks without seeming effort and irritation; but when it is falling or depressed, they seem sluggish and heavy, and respond badly or slowly to stimulation.

"I omitted to mention that during the spring 'climacteric' the proddings of sexual disturbance are apparent. Many of the men will have sexual sprees (masturbation) that bring them to a conditon resembling that of the 'fretful porcupine,' when they are in a condition to cast their quills at any one who may provoke or cross them. These sprees may be compared to the outbreaks of the paroxysmal drinker who carries his excesses to a point where the nervous system gives way under the strain and fails to assist him in his dissipation. A man will masturbate to that point where he is in a tremor, unable to eat or sleep, and on the border-land between sanity and insanity. Then we will have to take him in hand, and build him up as would be necessary in the case of a man recovering from an attack of alcoholism. These cases are, however, occurring at all seasons of the year."

If then we have shown that neurasthenia and suicide are more frequent in certain months of the year in various countries than in other months, when *á priori* they should be more frequent, shall we then conclude that temperature or its variation has anything to do with it? We are compelled to say that we do not think it has of itself much to do with the outbreaks or epidemics which we often see at this time. Moreover, we must further say that we believe no one knows what these influences are which disturb the equilibrium of the emotional nature. All we have been able to do is to call attention to the fact that climate and season do have a marked influence upon the manifestation of nervous activity in the various ways already indicated.

A CASE OF PERIOSTITIS, FOLLOWED BY OSTEO-MYELITIS, PYÆMIA, AND DEATH.

By C. M. HAY, M.D.,

ASSISTANT PHYSICIAN TO THE STATE INSANE ASYLUM, MORRISTOWN, N. J.

The following case seems to me to present several interesting and unusual features:

P. D., aged forty-five, laborer and soldier, with no history or evidence of syphilis or tuberculosis, was in good physical condition until November, 1888, during which month he sustained a slight contusion of the left tibia, about the juncture of its middle and upper third. The nature of the injury was a contusion, and the skin was only slightly broken, if at all. This resulted in an indurative periostitis, which slowly progressed until about three inches of the periosteum were involved in the process, and there was considerable infiltration of the surrounding tissues. Under treatment this inflammation partially subsided, but continued as a chronic condition, with some swelling and tenderness. It was at this time that I first saw the man, and since then the case was under my care in the hospital wards of this institution.

At this time the patient complained of pain through the limb, and the temperature and general condition of the patient indicated the formation of pus, so that, on December 27th, a free incision was made through the thickened periosteum, the deep layers of which had broken down into pus, while there was also superficial necrosis of the bone, which, at one point, extended deeply into the bone itself, and was connected with its medulla by a sinus. The medulla was then freely laid open, a small quantity of pus evacuated, and the wound packed.

In five weeks complete granulation and cicatrization of the wound had occurred, and the patient was apparently well. He continued well for about one week, when he began to have fever of from 100° to 102° F. at night for three nights.

On February 13th, the patient suddenly had a severe chill, followed by a temperature of 106° F., and an abscess suddenly appeared at the left elbow, and rapidly increased in size. Examination at this time revealed a normal condition of the heart, lungs, and kidneys, while the liver and spleen were not enlarged. The abscess was evacuated of about eight fluid-ounces of greenish, purulent pus, antisepticized, and drained. On the 16th phlegmasia dolens of the right leg occurred, a clot being plainly felt in the femoral vein. The temperature continued typical of acute pyæmia, with abrupt and extreme fluctuations, frequent chills and sweatings, a dry, brown-coated tongue, and adynamic nervous symptoms. The patient continued to sink lower into this typhoid condition, and it was thought he would soon die.

Under the free administration of brandy, quinine, turpentine, and digitalis he continued in the same condition, with high, irregular temperature, and quick, small, wavy pulse, with occasional chills and sweatings, until the 21st, when he began slowly to improve, and on the 24th the œdema had very much decreased in the right leg, and the abscess of the left elbow was rapidly healing. The patient's appetite had improved, while the fever was lower and more regular, ranging from 99° to 102°, with occasional subnormal falls. He continued in this condition until March 4th, when he began to have more fever, and to fail more rapidly in strength.

On March 6th phlegmasia dolens of the left leg occurred. The patient suddenly complained of agonizing pain in the left thigh, and in a few minutes the left leg became almost black in color, while a clot could be felt in the vein. Œdema of the member occurred in a few hours, and soon became extreme. The temperature became higher, and traces of albumin were found in the urine. Examination of the lungs revealed signs of consolidation at both bases posteriorly, while the respiration was markedly increased in frequency. The heart-sounds were rapid and confused, with great weakness of the first sound. On March 11th a small abscess formed in the subcutaneous cellular tissue near the seat of operation. This was opened and drained. On the 16th a large amount of pus (fully two pints) was evacuated from the right thigh just below Poupart's ligament, and the abscess was dressed antiseptically, with drainage. The patient again improved somewhat until March 20th, when all his symptoms increased in gravity; fluctuating tumors appeared in both iliac regions, and the perineum and scrotum became œdematous. The urine became more albuminous; new patches of pneumonia occurred; the heart-sounds became more rapid and more irregular; respiration varied from 30 to 50 in the minute, while the temperature ranged from 96½° to 105½°, and the patient died on March 29th, after some days of low, muttering delirium, with carphologia, subsultus tendinum, and extreme nervous symptoms.

Post-mortem examination ten hours after death. The body was emaciated, and there was œdema of both ankles; the left leg was more œdematous than the right. The brain presented no special lesions, and contained no abscesses. The heart was of normal size and appearance, but, on section, the muscular substance was friable, and very pale in color There was no valvular disease, and the cavities did not appear to be dilated.

The lungs were the seat of numerous scattered patches of pneumonia. These were more numerous in the right lung than in the left, but the lower lobes posteriorly of both lungs were extensively infiltrated. The apices of both lungs were free, and, elsewhere than immediately surrounding each of these patches of consolidation the lungs were anæmic. In the right lower lobe, these pyæmic patches were older than elsewhere, and numerous small abscesses, varying in size from the head of a pin to one and a quarter inches in diameter remained. Fewer abscesses were found in the left lung, where the patches were also numerous, and seemed of recent occurrence.

The liver was symmetrically enlarged, and pale; capsule not adherent; contained no abscesses. The substance was friable, and there were numerous ashen-white patches disseminated through the substance of the organ, giving it a mottled appearance. These patches were from one to three inches in diameter, and were of various shapes.

The kidneys were enlarged; capsule not adherent, cortex not diminished. They showed the same ashen-white patches as were seen in the liver. The spleen was enlarged, capsules presented signs of recent peri-splenitis, while the interior of the organ was simply a pus cavity. The contents were liquid, of a greenish-black color, and gangrenous odor. The condition suggested multiple abscesses which had coalesced.

No gross lesions of the stomach, intestines, or pancreas were found. The arteries were healthy, as far as examined. They were in a state of contraction, and contained long fibrous coagula.

A small abscess was found on the left leg, posteriorly, and contained one fluid-ounce of purulent pus. On section, the abscess in the right thigh (which had been opened below Poupart's ligament) showed that it was very extensive, extending internally deeply under the abductor muscles, and externally beneath the deep fascia, while the femoral artery and vein, and profunda femoris, with their branches, ran free through the abscess. Instead of any reparative process, actual sloughing had occurred. From this abscess a sinus, formed between the femoral artery and vein, and posterior to both, communicated with the abscess in the iliac fossa, and this latter was found to be connected with centres of suppuration in the psoas and lumbar regions.

The veins, as we should expect, presented the most marked lesions. The superficial veins of the lower portion of the abdomen and both thighs were distended to three or four times their natural size, and formed a rich, varicose anastomosis here, and also, to a less extent, over the thorax and neck. This network of greatly distended veins contrasted

markedly with the blanched surface of the skin. The condition of the deep veins was as follows:

The right internal jugular was almost completely occluded by firm coagula, which adhered to one side of the vessel, for the distance of three inches. During that extent the vessel was greatly thickened. At the juncture of the right internal jugular and the right subclavian veins, behind one of the valves, was found a very firm thrombus. There was, however, no distinct change in the wall of the vessel at this point. Coagula, which were unusually firm, were also found in the left internal jugular and left subclavian, innominate, transverse veins, and the superior vena cava. These communicated with a similar coagulum in the right auricle, and probably occurred with death, while the one found in the internal jugular seemed to be the result of previous phlebitis. The principal lesions were in the inferior vena cava and the veins of the lower extremities.

The following veins were chiefly affected: The inferior vena cava, from the juncture of the iliacs to its juncture with the left renal vein; both common and external iliacs, and both femoral veins, with their main branches, down as far as examined below the knee. The lesions were essentially of the same nature throughout, only differing in degree. These consisted of thrombosis, partial organization of the clot, with its subsequent softening, formation of pus, with thickening of the walls and resultant ulceration of the affected veins. The right femoral vein, as it ran through the abscess below Poupart's ligament, had been converted into a fibrous cord, and the organization of the thrombus here appeared complete. The right external iliac was filled with pus and broken-down fibrinous shreds, while an opening half an inch in diameter, involving one-third of the circumference of the vein, communicated with the iliac and psoas abscesses. The right common iliac, and the inferior vena cava presented signs of acute phlebitis, and were filled with purulent pus, the line of the vessels being one ulcerating surface, while the walls of both were three or four times thicker than normal. The left external iliac vein was the seat of pyo-phlebitis, the vein being enormously distended to many times its original size, but the vessel wall was intact. The left femoral vein was thrombosed to below the knee, but softening had occurred only at a few points, and the lining of the vein was not inflamed. There was no formation of pus in any of the tissues outside the veins in the left iliac region, thigh or leg.

Longitudinal section through the left tibia showed purulent osteo-myelitis of the bone above and below the seat of operation, while at the seat of operation itself the medullary canal was filled with new bone, and for a distance of four inches the bone was perfectly healthy. There was also some serous effusion in both knee-joints, but they were not inflamed. The inguinal lymphatic glands were much enlarged on both sides, but suppuration had not occurred in or about them.

Microscopic examination of the light-colored patches in the liver and kidneys revealed amyloid degeneration, while in the latter organ the signs of acute parenchymatous nephritis were evident. Section of some of the smaller pyæmic patches showed the ordinary appearance of pneumonic consolidation, to which, however, were added capillary hemorrhages. Transverse section through one of the inflamed veins gave the ordinary appearance of acute suppurative phlebitis. The thickening of the left femoral vein, just below Poupart's ligament, was remarkable, the wall of the vein being over a quarter of an inch thick. Microscopically it was infiltrated with leucocytes, the principal thickening being in the adventitia of the vessel. The intima was entirely gone, and ordinary granulation tissue surrounded the lumen of the vessel itself. The interior was filled with pus cells, compound granule cells, shreds of fibrine, and granular matter, mixed with the coloring matter of the blood.

The above case seems of great interest in many respects. The slight nature of the traumatism, which apparently was the primary cause of all the subsequent symptoms, certainly points very clearly to the necessity of prompt treatment in all such cases. My chief reason, however, for reporting this case is the fact that acute pyæmia occurred after complete closure of the wound, and after the man had apparently recovered his usual health. The post-mortem sections of the affected bone conclusively proved that that part of the bone upon which the operation had been performed had been entirely repaired, and at the same time revealed new foci of suppurative osteo-myelitis above and below that portion of the bone. Whether these were the remains of the primary inflammation it is hard to say; that they existed at the time of operation seems improbable, on account of the rapid and complete closure of the wound and the recovery of the patient. It would certainly appear that these foci began with the subsequent evening fever, and that they were the initial lesions from which the abscess at the left elbow originated. The violent onset of the disease in its most acute type makes it probable that at this time the spleen was also the seat of pyæmic lesions, and the absence of any lung implication strengthens this view.

The manner in which the collateral circulation was established for the lower extremities, and its efficiency for such a long period of time, are worthy of note, while the very extensive secondary inflammations, which must have existed for weeks prior to death, also add interest to the case.

The sequence of events in this patient's case seems plain, provided we assume that the blood became primarily affected from the purulent osteo-myelitis, which in some manner occurred in the tibia after the closure of the wound. The condition of the spleen, as has been said, would indicate that it was next affected, and the widespread thrombosis and embolism (as evidenced by the condition of the lungs and spleen and the successive attacks of phlegmasia

dolens) seemed to have been the primary condition in the various situations in which they occurred, while the phlebitis was undoubtedly secondary. This was very clearly indicated by the acute attacks of phlegmasia dolens, with the subsequent formation of abscess in those situations, and also by the fact that many large veins with healthy walls were found thrombosed at the autopsy. The occurrence of phlegmasia of the left lower extremity exhibited this most markedly. Thrombosis attended by pain, cyanosis, and gradual œdema of the member occurred on March 6th, but it was not until March 20th that the condition of pyo-phlebitis of the left external iliac vein made itself manifest as a fluctuating tumor.

The recovery from the acute symptoms, and the continuance of the case as one of chronic pyæmia for such a long period of time, together with the late occurrence of septic pneumonia, justified the hope for a while of the patient's ultimate recovery, which was however speedily dismissed by the occurrence of the secondary complications already enumerated. It seemed surprising that ulcerative endocarditis did not occur in the case, when we consider the condition of the inferior vena cava itself.

In connection with the veins, I neglected to state that both the vena azygos, superior and inferior, with the intercostal and lumbar veins, were found greatly dilated.

In conclusion, my thanks and indebtedness are due to Dr. Gilbert B. Pfoutz, pathologist at this institution, for valuable aid in the microscopic study of this case.

THE PINE BELT OF NEW JERSEY—A REGION OF SANDY SOIL AND PINE FORESTS.[1]

BY ISAAC HULL PLATT, M.D.,
OF LAKEWOOD, N. J.

NEW JERSEY, though a small State, presents a diversity in its topographical and geological features. In the northern portion it is traversed by the Kittatiny and Highland ranges of hills, parts of the great Appalachian chain; the central portion is characterized by red sandstone with trap ledges, while the southern and eastern part of the State consists of level country, with a sandy soil and pine forests. Along the shore there are long stretches of shallow bays and tide marshes, and in the extreme southern portion many little rivers with wet meadows lying along their banks, but running through the interior of the State there is a strip of land about sixty miles in length and from eight to twenty miles in breadth, reaching from a few miles south of Freehold, in Monmouth County, almost to Vineland, in Cumberland County. This comprises the inland portion of the sandy tract, excluding the extreme southern portion, of which I have spoken as being damp. This region has long enjoyed a local reputation for healthfulness, and some portions have been mainly settled by people who have sought it for that reason. Its soil varies somewhat in its character, ranging from a light sandy loam to clear beach sand. Its streams, which are sufficient for drainage, have good banks which they very rarely, if ever, overflow, and there is no wet meadow. There are a few peat bogs which have been partially utilized in the cranberry culture, and also some marl beds in the northern portion, and occasionally a cedar swamp, but these features are all of very limited extent. Leaving these out of account the richest soil is a light sandy porous loam, containing about 85 per cent. of silica and only 1½ per cent. of water, while the lightest is almost pure quartz sand, 95 per cent. silica and only 0.6 per cent water.[1] Extensive pine forests are a prominent feature of this region. They have been in some places cut off or burned, and in some spots are replaced by oak and other deciduous trees, but there are enough left to make it pre-eminently a pine region. One consequence of the sandy nature of the soil is the entire absence of mud. Of course, during a rain or a thaw there is wet sand, but it is no more like mud than the wet sand of a sea beach, and within a few hours after the cessation of the rain it is dry again. Melting snow does not produce slush, except in rare cases where the snow has immediately followed a freezing rain, as the dry and thirsty soil drinks up the water as fast as the melting of the snow can produce it. I have seen eight inches of snow disappear so completely in twenty-four hours that one could walk out, "across lots," with thin shoes without moistening the feet. Owing to the coarseness of the sand there is no dust, except a slight amount in very dry weather where the roads have been covered with clay or gravel.

The importance of soil dryness as a climatic element in the prophylaxis of phthisis is too well known to need rehearsal. The researches of the elder Bowditch, Buchanan, Simon, Pepper, and others are familiar. Why soil dampness should have an influence in the production of phthisis, so out of proportion to dampness emanating from other sources, I have never seen satisfactorily explained, and it is not my purpose to attempt its explanation, but I think some figures from the vital statistics of New Jersey will help confirm the fact if any confirmation is needed.

The tract which I have described, comprising parts of the counties of Monmouth, Ocean, Burlington, Camden, and Atlantic, is coëxtensive with the townships of Howell, Jackson, Manchester, Southampton, Woodland, Shamong, Winslow, and Ham-

[1] Read before the American Climatological Association, June 24, 1888.

[1] Cook's Geology of New Jersey.

monton. In all, about 570 square miles, containing a population, according to the State census of 1885, of 14,475. According to the reports of the State Board of Health, which are carefully prepared and I believe as accurate as any statistics of the kind, the whole number of deaths in these eight townships during the six years from 1883 to 1888, inclusive, was 1057, or an average of 12.16 per thousand, a year. The number of deaths from consumption was 141, or 1.6 per thousand, a year. In the State of New Jersey, during the same period, the total mortality was 18.65 per thousand, and the mortality from consumption 2.53 per thousand, or, throwing out towns of over five thousand inhabitants, the total mortality was 15.07 per thousand, and the mortality from consumption 2.12.

	Total mortality per thousand.	Mortality from consumption per thousand.
Sandy tract	12.16	1 60
N. J. State	18 65	2.53
N. J., excluding cities	15.07	2.12

The comparatively low mortality from consumption will be rendered more striking if attention is called to the nature of the population of the region. The inhabitants may nearly all be included in two classes: the descendants of the original settlers and those who have sought this region because of its supposed healthfulness. Probably owing to the sterility of the soil, the native south Jerseyman is very poor; he resembles in many respects the poor whites of the southern States. He can in many cases neither read nor write. His surroundings are as unhygienic as poverty, ignorance, and lack of ambition can readily make them in a naturally healthy region. His home is a hovel and his food indigestible, and often insufficient and innutritious. Of course, there are exceptions, but this is the rule. Both this class and that composed of people who have come because they were in feeble health would naturally be supposed to raise the death-rate from phthisis.

The comparison with the rest of the State of New Jersey I regard as of greater importance than that with any place else, because the statistics are compiled under the same general direction and under the same rules and conditions; but it will, perhaps, be interesting to cite for comparison a few other death-rates from phthisis:

New York City	3.56
Philadelphia	3.16
Brooklyn	2.98
Boston	3.34
San Francisco	3.06
Massachusetts	2.90
New York State	2.50
London	3.20
Rural England	2.30
Switzerland	1.80
Rural Victoria (Australia)	0.87

It is to be regretted that no systematic meteorological observations have been made in this region. The nearest approach is the record of Vineland,[1] just south of the region described and in quite similar country. This for ten years from 1878 to 1888 is as follows:

Barometer, reduced to 32°,	
Mean	29.92
Maximum	30.76
Minimum	28.65
Thermometer,	
Mean	53 60°
Maximum	104.00
Minimum	—10.00
Mean relative humidity	72.2
Rainfall per annum,	
Mean	47.41
Maximum	59.99
Cloudy days, average	107.00

There is nothing very striking in this table; the mean relative humidity is moderate, therefore the climate cannot be classed as very dry. In spite, however, of the fact that by the tables the humidity does not differ materially from that of New York or Boston, the sensation of dampness is far less. In winter, the peculiarly disagreeable weather accompanying an east wind in our seaboard cities, and known as "raw," is almost unknown, and in summer, while the weather is frequently warm it is rarely sultry. The east wind even in winter loses its disagreeable character which makes it a bane to the Bostonian and New Yorker, and in warm weather is the pleasantest wind we have, coming as it does with the freshness and coolness of the sea, but deprived of its dampness by the stretch of sand and pine forest over which it has passed. Fogs are very rare. In a three years' residence at Lakewood I have not seen more than five or six, and these were dissipated a few hours after sunrise.

The village of Lakewood lies near the western border of the township of Brick in Ocean County, ten miles from the sea. It is not included in the region to which the statistics given above apply, because it is part of a statistical division extending to the seashore, and also because a large proportion of the deaths there are of patients from a distance. It is, however, practically a part of the region described, being within a mile of its border and identical with it in soil and climate, and is the only place thereabout where good accommodations can be found for sojourners. The elevation of the village above the sea level is from sixty to a hundred feet, it being situated on the southern slope of a low ridge which forms a shelter from the northerly and northwesterly winds.

[1] Vineland is almost identical in its physical features to the region under consideration. The reason of its exclusion is the existence of a strip of damp soil between.

On the north and west the village streets terminate in the pine woods which, with an occasional clearing for farming purposes, extend several miles northward and indefinitely to the west. To the south and east the country is more open, but a large portion is still covered with pines. The town is furnished with water from the Metedeconk River, which flows just to the south, and is supplied with a good system of drainage.

There is one feature of Lakewood which has not yet received the attention due it, and in fact the existence of which I have only recently become aware, and that is, a very remarkable spring about a mile from the village. It is of the class of the Poland and Bethesda springs, and has an estimated flow of from sixty to ninety gallons per minute. The following is its analysis:

Total solids . . .	grs. per gallon,		1.0260
Silica	" "	0.2098	
Sodium chloride . .	" "	0.4431	
Ferrous sulphate . .	" "	0.1107	
Calcium sulphate .	" "	0.0495	
Calcium chloride .	" "	0.0058	
Potassium chloride .	" "	0 0220	
Magnesium chloride .	" "	0.0547	
Mineral residue . .	" "		0.8956
Organic and volatile matter	" "		0.1304

The analysis of the Poland spring I will give here for comparison:

Total solids . . .	grs. per gallon,		3.6759
Sulphate of potassium	" "	0.1562	
Chloride of sodium .	" "	0.2636	
Carbonate of sodium .	" "	0.1333	
Carbonate of lime .	" "	1.2287	
Carbonate of magnesium	" "	0.5412	
Oxide of iron and aluminum	" "	traces	
Silica	" "	1.1197	
Organic and volatile matter	" "	0.2332	

It will be seen that in the quality of purity the Lakewood spring excels the Poland spring by more than three times. Accepting the views of the profession as to the value of pure spring water in the treatment of Bright's disease, as epitomized by Dr. Andrew H. Smith in his paper read before the Climatological Association last year, and in view of the undoubted benefit of the water from the Poland and other similar springs in these cases, the value of this spring can hardly be doubted. I have not yet had an opportunity to put this theroretical opinion to a clinical test, but I shall do so as soon as possible, and in view of the exceedingly clear course of reasoning by which Dr. Smith reaches his conclusions in the paper referred to, and of experience with water of similar springs I have little doubt of the result.

It is not my intention to enter into any comparison of this region with more famous health resorts. I certainly believe that the high altitude of the Engadine or Colorado has positive advantages which places near the sea level cannot possess; but there is a long list of contra-indications to the high altitude treatment, and there are many patients who cannot avail themselves of it for various reasons. To such our region offers a refuge with the very decided advantages of an exceedingly dry, porous soil, the environment of pine forest, good accommodation and easy accessibility from the great centres of population. It is most admirably situated for carrying out the idea advanced by Dr. Bowditch at our meeting last year, of residence in comparatively favorable regions near at home, where sanitaria might be established, and climatic, medical, and hygienic treatment combined without the necessity of a distant exile.

As some future time I hope to be able to give something more definite in regard to the results of treatment in this region, but as yet my observations are not sufficiently extensive or long continued. I can only say at present that it is very exceptional for a patient with bronchial or pulmonary disease not to derive some benefit greater or less from the change, and in many cases the benefit has seemed remarkable.

MEDICAL PROGRESS.

Biborate of Soda in Epilepsy.—The objections to a long-continued use of the bromides in epilepsy are well known. Substitutes are eagerly sought after. Of the biborate of soda for this purpose, Dr. J. D. Munson, Medical Superintendent of the Northern Michigan Asylum, in his last report, which we quote from the *American Lancet* for July, says:

"It has been found quite equal to the bromides in controlling the seizures. In some cases it has been found superior. It is prompt in its action, and does not affect badly the general condition, and is usually well borne after the first few doses.

"Biborate of soda tends to constrict the peripheral bloodvessels in a remarkable manner, and to this action is doubtless due its beneficial action in epilepsy. In epileptics with high arterial tension, borax is sometimes harmful, while in those with low arterial tension, but strong heart action, it is most apt to be useful."

In cases with weak heart it acts badly, probably by its vaso-motor action, obstructing still more the outward blood. Among the drawbacks to its use, he gives the following:

"Given regularly in moderate doses it is apt to affect the nutrition of the scalp, the hair becoming rough and brittle, and in one or two cases alopecia has followed. A troublesome psoriasis is occasionally induced, which, according to our experience, has not yielded readily to treatment, nor has the administration of Fowler's solution with it always prevented its appearance. In one case a suppurative inflammation of the middle ear was always induced by the use of the biborate."

He advises that the drug be never given before meals, or for long periods continuously. It is well sometimes to alternate its administration with those of the bromides.

Nephrectomy in Case of a Horseshoe Kidney.—Socin, of Bâle, performed an exploratory operation last year on a woman, aged forty-seven, who had been subject for thirty years to pains in the right hypochondrium, where a tumor had gradually formed. He aspirated, and found that the swelling contained urine; then he performed nephrotomy. Hydronephrosis was discovered during the operation. The urine passed by the urethra remained normal, but on and after the fourth day an abundance of turbid urine drained from the opening made in the kidney, and an examination led to the conclusion that parenchymatous nephritis and purulent pyelitis were present. On May 12th nephrectomy was attempted. After an abdominal incision and successful ligature of the structures in the hilum, it appeared that nothing was left to do besides setting free the lower part of the diseased kidney. On careful manipulation this extremity was found to be continuous with a bridge of renal tissue, which passed over the aorta and vena cava and joined the lower part of the left kidney. This bridge or isthmus was found to be but loosely connected with the great vessels. Dr. Socin divided it by means of the thermo-cautery, so that the right side of the horseshoe kidney came away. Five ligatures were applied to bleeding points on the raw surface left behind, which was then covered over by the capsule, the edges of the latter being united by sutures. An abdomino-lumbar drain was applied. The patient was in excellent health four months after the operation. In Braun's (Heidelberg) similar case a horseshoe kidney was discovered at operation for the removal of a pyonephrosis. The isthmus adhered strongly to the vena cava; on attempting to separate them, profuse venous hemorrhage occurred, which was controlled with difficulty. The patient sank from exhaustion at the end of the operation.—*British Med. Journal*, July 13, 1889.

Treatment of Spasmodic Croup.—The treatment indicated in spasmodic croup is, first to overcome the suffocation, and later to abort the paroxysms. The *Revue général de Clinique et de Thérapeutique*, of June 13th, suggests the following treatment:

1. Before or during the paroxysm an emetic should be given; this will facilitate the removal of the mucus in the throat.

2. Mild cutaneous counter-irritants should be used; such as hot-water fomentations applied to the throat. Hot baths are frequently of considerable value.

3. After the paroxysm a dessertspoonful of the following prescription should be administered every half hour:

℞.—Oxysulphuret of antimony, grs. ¾ to 1½.
Spirits of aconite root } āā gtts. v. to x.
Tincture of belladonna }
Syrup of orange flowers . f℥j.
Distilled Linden flower water f℥jv.—M.

Disinfection of Springs, and Number of Germs in Groundwater.—Dr. Carl Fränkel, in the *Zeitschrift f. Hygiene*, reports a series of experiments made by him to determine some points of practical importance, namely, What are the relative values of tube wells and pot wells, and can they be disinfected by the measure usually recommended?

With regard to tube wells, from their mode of construction they are not liable to contamination from surface impurities, as the pot wells are, and it becomes of the greatest consequence to know whether they receive infective microörganisms from more distant sources. The result of these experiments is that, as a rule, the water entering tube wells is absolutely free from microorganisms. But it still appears that a growth of microörganisms takes place in the tube wells, and a consideration of all the circumstances points to the growth of a pellicle of microörganisms clinging to the sides of the tube. Hence, one way of disinfecting the tube wells is to brush them clear, and then completely pump off the turbid liquid. In cases where this proceeding proves inadequate, a concentrated solution of carbolic acid and sulphuric acid dropped into the tube, and left for a day or two, will complete the disinfection. Disinfection of these wells by lime is quite unsuitable, as it forms a mortar, and seriously interferes with the entrance of water.

The ordinary pot well, on the other hand, is incapable of disinfection, and Dr. Fränkel agrees with Plagge that it is a hygienic monstrosity. Considering how common pot wells are in our country districts, these are results which require careful attention.

The tube wells, which Dr. Fränkel found to furnish water freer from germs, were sunk in a part of Berlin which, at first sight, would seem to expose them to great risk of infection. In reality, however, after a time, a thick pellicle forms in old soils, which effectually precludes the passage of germs beyond a certain depth. Two sources of error have here to be guarded against. In the first place, the pellicle or its equivalent, which prevents the passage of germs downward, may be broken through at some point, or the corresponding ground may be constituted in parts of pebbles or gravel, which allows of the transmission of microörganisms; and, in the second place, the chemical constitution of the water passing away from these old soils will very likely be such as to lead to a free growth of microörganisms, as was the case in these experiments. It is practically impossible to exclude all access of microörganisms to the well.

The chief conclusions to be drawn from Dr. Fränkel's experiments are, that Abyssinian or tube wells are infinitely preferable to the ordinary pot well, and that a disinfection of the tube in the manner indicated above is, as a rule, all that is necessary to make the water quite free from microörganisms.—*The Medical Chronicle*, July, 1889.

Creolin-eczema.—Encouraged by the universal praise and reported innocuousness of creolin, Dr. J. Wackez, of Munich, used the drug as a dressing for wounds in children. In seventeen cases of minor wounds in which he used creolin gauze as a dressing, ten healed by first intention; the remaining seven, however, developed an eczematous rash in the neighborhood of the wound, which closely resembled the rash of scarlet fever, and which occasioned severe itching. On the third day the skin became raised by numerous blisters, some of which were as large as a dollar. These blisters were filled with a clear liquid. The temperature of the skin was high, the neighboring lymphatics enlarged; the general condition of the patient was also considerably affected, there being loss of appetite, headache, and in some cases even vomiting. After the blisters had dried up, large

lamellæ of the epidermis were shed; in one case the entire surface of the palm of the hand and the volar surface of the fourth finger, which gave the hand the appearance of a burn. In all the cases creolin (Pearson's) had been used in solution 1 to 1000, the application being made with gauze soaked in the solution.

Dr. Wackez made further experiments with the drug on a boy, both hands of whom had been injured, and found that the hand dressed with creolin gauze developed similar eczema as observed in the other cases, whilst the opposite hand, which had been dressed with carbolized gauze, healed rapidly, without any unpleasant symptoms.—*Therap. Monatsh.*, June, 1889.

Lotion for Pityriasis.—DR. HILLAIRET and ZAUCHER, in *L'Union Médical*, of June 18th, give the following potion, claiming it to be of special value in cases of pityriasis alba:

℞.—Hydrate of chloral . . 3 parts.
Glycerine } . . āā 25 "
Alcohol }
Water . . . . . 100 " —M.

Sig.—Apply as a lotion to the affected parts, at first daily, later every two days, and then once a week. Its use should be decreased according to the improvement. When the disease is of an eczematous type, vapor baths or local hot-water sprays will be found useful.

Laminaria in Stricture of the Œsophagus.—We read in the *British Medical Journal*, of June 22d, that PROFESSOR SENATOR has recently stated that for about a year past he has used laminaria in stricture of the gullet with comparatively good results. A piece of laminaria is attached to the end of an ordinary œsophageal bougie, and for greater safety this is further connected with a string running through the whole length of the bougie. Different sizes are used according to circumstances. The instrument is passed into the stricture and left in position from half an hour to an hour, during which time the laminaria swells to a considerable extent. In one case it expanded from one to one and a half millimetres in the course of half an hour. The surface of the laminaria remains smooth, and does not injure the mucous membrane. In most of the cases in which Dr. Senator has tried this plan the stricture has been cancerous, and, as he says, although "by gradual and frequently repeated pressure a carcinoma may cicatrize and become atrophied, this very seldom happens." In a large proportion of his cases, however, the treatment produced very marked dilatation of the stricture, so that the patients after a certain time could swallow much better than before. In some instances there was no improvement, and Professor Senator confesses that at first his anxiety to dilate the stricture as quickly as possible made him apply the treatment without sufficient regard for the tolerance of the diseased parts. If due care is not exercised, the laminaria may swell so much as to cause great pain, and even difficulty in removal. The most favorable cases for the treatment are, of course, those of cicatricial stricture. Dr. Senator points out that laminaria may also be used with good effect in narrowing of other canals, and he relates one case of stricture of the rectum in which he tried it, but apparently with indifferent success.

Stomachic Mixture.—The *Revue de Thér. Méd.-Chir.*, June 1, 1889, gives the following stomachic mixture:

℞.—Compound tincture of cardamom . . . .
Tincture of vanilla . .
Tincture of absinthe . .
Tincture of canella . .
Tincture of ginger . .
Tincture of quassia . .
Tincture of calumbo . } āā ℥ijss.—M.

Sig.—Twenty-five drops before meals.

Hydracetin and Psoriasis.—Pure hydracetin, or, more correctly, acetyl-phenyl-hydracetin, is a white, crystalline powder, both tasteless and odorless. It dissolves but slightly in water, but is easily soluble in alcohol in proportions of 1 to 50. DR. GUTTMAN has noted its active therapeutic properties in psoriasis. In one case seven applications of a 10 per cent. ointment of hydracetin cured a case of severe psoriasis of the back; and in another case complete recovery resulted within a week. In neither case was any recurrence of the disease noted. —*Monatsheft f. Prak. Dermat.*, July, 1889.

The Vitality of the Cholera Bacteria in Milk.—Some time ago, the crew of a ship, at Calcutta, became infected with cholera. The infection was traced to the fact that the milk, which had been taken on board at Calcutta had been adulterated with water drawn from a tank which was proved to be infected with cholera excrements. In order to ascertain definitely the vitality of the cholera bacillus in milk, DR. S. KITASATO, of Japan, who is now working in Dr. Koch's laboratory, undertook a series of experiments, the results of which are reported in the *Centralb. für Bakter. und Parasit.*, June 14, 1889.

Unsterilized milk was, soon after being milked, placed in test-tubes and infected from cultures of cholera bacilli. The different tests were kept at various temperatures and subjected to hourly examinations. In all cases the bacilli died as soon as the milk became sour. In the tests which had been kept at a temperature of 97° F., the bacilli died inside of 14 hours, whilst in those kept at a temperature of 46° or 54° F. lived, at the longest, only for three and one-half days. In milk sterilized by boiling in a steam bath for four or five hours, the bacilli lived longer, as the milk kept fresh much longer. At a temperature of 97° F., the milk soured very gradually and the bacilli died in two weeks, the milk at the expiration of that time being found germless. When kept at a temperature not over 71° or 77° F., living cholera bacteria were found in the tests for three weeks.

Kitasato says that he found that if milk be boiled for five minutes in a water bath, its sterilization will be complete.

The Administration of Cod-liver Oil.—For the purpose of agreeably modifying both the odor as well as the taste of cod-liver oil, DR. SEIG, in the *Revue de Thér. Méd.-Chir.*, June 1, 1889, recommends that it be given in the following formula:

℞.—Cod-liver oil . . . . . f ℥lxx.
Creasote . . . . . ♏xl.
Saccharin . . . . . grs. ijss.—M.

The odor of this preparation will resemble that of roast meat.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, AUGUST 10, 1889.

THE FUNCTION OF DIGESTION IN PULMONARY PHTHISIS.

SYMPTOMS of digestive disturbance are prominent in every stage of phthisis, and sometimes occupy the foreground of the clinical picture. This is so well known that certain writers recommend a careful examination of the lungs in all cases of dyspepsia, especially in young people, and the term "latent dyspeptic phthisis" has been applied by Sée to cases of which the first symptoms are all referred to the digestive organs. In some cases, however, notwithstanding the presence of marked loss of appetite, and other symptoms of digestive disturbance, the functional capacity of the stomach is good, as is proved by the success attendant upon the treatment of this disease by forced alimentation.

Until quite recently there have been no criteria by which to discriminate the cases in which benefit may be expected from this treatment from those in which failure is sure to attend it. In two successive numbers of the *Deutsche medicinische Wochenschrift* (Nos. 14 and 15, 1889) DRS. O. BRIEGER and C. H. HILDEBRAND have published the results of their examinations of the gastric secretions in a number of cases of phthisis, and arrive, in the main, at similar conclusions. They differ somewhat, however, with reference to the causes of the digestive disturbances, Hildebrand referring them almost exclusively to fever, while Brieger simply mentions that, in two cases, hydrochloric acid, which had previously been present in the gastric secretions, disappeared with the onset of fever.

Of the 64 cases examined by Brieger, 31 were severe, with continuous fever; 27 moderate, with more or less fever; and 6 in an early stage without fever. In 16 per cent. of the first group the chemistry of digestion was normal, while in the remainder there was more or less gastric insufficiency; and in 9.6 per cent. there was a complete absence of the normal products of gastric secretion. Of the second group, the secretions were normal in 33 per cent.; in the remainder were more or less abnormal, while in 6.6 per cent. the normal secretions were absent. In the third group, the cases in which the gastric secretions were normal equalled in number those in which they were impaired.

Brieger attributes the digestive disorders of phthisis to chronic glandular gastritis, but brings no decisive anatomical proof to the support of this opinion. In the fatal cases necropsies were performed so long after death that it was impossible to distinguish ante- from post-mortem changes. His opinion that anæmia is the cause of digestive disorders in the earliest stage of phthisis we believe to be destitute of proof. It is only in the high grades of anæmia that digestive disorders can be said to depend directly on the impoverished state of the blood; and in phthisis, even in late stages, the anæmia is surprisingly slight—not to be compared with that of cancer of the stomach or intestine, or with that of pernicious anæmia. In the early stages of phthisis the anæmia is generally trivial.

Hildebrand's opinion, that the indigestion of phthisis is caused by fever, is less open to criticism. In one group of cases—the whole number was forty—hydrochloric acid was always present in the gastric secretions; in a second, it was never present; and in a third it was sometimes present, sometimes absent. These differences were all dependent on the presence or absence of fever. In the first group there was no fever; in the second it was continuous; and in the third it was intermittent. Hildebrand concludes from his experiments, that 100.2° F. is the temperature line at and above which free hydrochloric acid is absent from the gastric secretions.

These observations are, it is reasonable to hope, merely the beginning of more extended researches, not only in phthisis, but also in other chronic diseases. From the facts thereby obtained, the physician may be enabled to substitute for vague suggestions, precise directions with reference to diet, and to

arrange its details, not only with general reference to the disease, but with particular adaptation to the needs of the patient.

SUMMER RECREATION.

A COMPARISON of the present with the comparatively recent past shows a marked change in the habits of the people, particularly of our cities, with respect to summer recreations. The fashion of leaving home for a greater or less period during the summer season has become of very general observance, and is not confined to populated centres, or to the well-to-do or wealthy classes. Those in every avocation in life, from the humblest to the most responsible, expect and take a summer vacation. As a consequence of this popular demand, certain practices have sprung up, such as the early closing of places of business, the Saturday half-holiday, which is legalized in some States, the regular summer vacation to employees, and the increasing number of legal holidays.

The immense facilities for the accommodation of pleasure-seekers scattered all over the country, in the mountains, in the country, and by the seaside, which are being constantly extended, are being taken advantage of by an enormous number of people, coming and going throughout the season. They exist because of the great and ever-increasing popular demand for such accommodations. There are also the excursions by rail, by steamboat, and by steamship across the ocean for travel in foreign countries, which have increased so greatly as to make the summer season the harvest time for railroad and steamship companies. Those too poor to enjoy an outing are provided for liberally by such institutions as the Children's Country Week, fresh air societies, sanitarium associations, and the like.

The rapid increase of population partly explains the great multiplication of places of summer resort. But there is beyond this the fact, patent to every close observer, that a change is taking place in the views and practices of the people. The American people are fast becoming a pleasure-seeking people. The enormous increase and the great distribution of wealth provide for the gratification of this inclination, if they do not create it.

The necessity of relaxation from the intense business activity which characterizes American life arises from the demands of natural laws. Diversion of mind and rest of body recreate and restore exhausted functions, and prevent more permanent disability. The more active, taxing, and prolonged the mental and physical strain, especially if immoderate, the greater the necessity for rest and diversion, if the mental and physical health are to be maintained. The yearning for rest is based upon physiological laws. It is a fundamental feature of the Sabbath, divinely ordained for rest and worship.

The increasing tendency among an active, industrious, and energetic race to relax occasionally their labors, must be looked upon, from a hygienic and social standpoint, as of much advantage to the health and prosperity of the people. It is necessary, however, that the true object of the vacation is not perverted by immoderate indulgences and excesses of whatsoever kind, and that care and good judgment be exercised in selecting a suitable and healthy environment. There is need of caution to the seekers after health and recreation. Quietude and absolute rest of body and mind are the best restoratives to many who are jaded by incessant cares and worry. Others require the stimulus of out-door physical exercise, but it should be judiciously employed. It is a mistake to enter too actively upon a course of unaccustomed exercise. The system when enervated cannot respond to excessive demands, and the overstrain tends to weaken rather than strengthen enfeebled functions.

Excesses committed under the exhilaration of pleasure are to be guarded against as defeating the aim of healthful recreation. The exactions of society, if permitted to sway the coveted vacation, simply transfer the scene without altering the conditions, and depress and exhaust vitality, and render bad worse. The sources of disease often lurk in the shadow of the summer resort. It is therefore very necessary to look critically to the sanitary advantages of the place of sojourn. A healthful environment and a house with correct sanitary appointments are among the most important objects of selection. Wholesome water and safe drainage cannot be dispensed with. The absence of these essentials too often makes the summer experience a most disastrous one.

Immoderate surf-bathing, excessive indulgence at table, and constant encroachment upon the hours allotted to sleep, are violations of hygienic laws which are sure to demand a penalty. The *Lancet's* advice to the professional man, to turn his back upon the throngs of the summer resort and escape its wearying demands, and with few or no companions, except perhaps a faithful dog, seek an un-

frequented path, where diversion is pronounced and satisfying, is sage advice which the experience of many will endorse.

THE PREVENTION OF HOG CHOLERA.

In another column we present the conclusions reached by the Board of Inquiry, consisting of Drs. E. O. Shakespeare, R. Meade Bolton, and T. J. Burrill, appointed by the U. S. Commissioner of Agriculture to study the causes and prevention of hog cholera and swine plague. This inquiry was wisely instituted by the Department of Agriculture, with the view of obtaining such information as would enable it to restrict the spread of diseases which, according to accurate information, already cause a loss in this country of upward of twenty-millions of dollars every year.

It is a subject for congratulation that such competent men were secured for this difficult investigation, but it is a matter for deep regret that the money at the disposal of the Department was not sufficient to enable the Commission to complete its work. The results already obtained give reason to hope that the threshold of a discovery leading to important practical and economic results has already been crossed.

The Commission finds that the germs of hog cholera and of swine plague have been now clearly described and identified; that disinfection as a means of prevention cannot be made effective under the existing conditions; and that, with our present knowledge, treatment is futile. The real hope for the restriction of the disease probably lies in some form of preventive inoculation, but further investigation is necessary before this can be recommended, since every hog thus treated becomes, for the time being, a new centre of possible infection and, furthermore, inoculation of the living germ seems permanently to stunt the growth of the animal.

The Commission points out the important fact that the chemical products of certain pathogenic germs in artificial cultures possess the same protective power as do the living germs themselves, and their own uncompleted investigations seem to indicate strongly that this is true in reference to the germ of hog cholera. If further investigations confirm this, a safe, harmless, efficient and practical means of preventing hog cholera will have been found.

The objects sought for by this investigation are so important to the agricultural and economic interests of the country and the outlook for the early attainment of valuable results is so encouraging that the work of the Commission should be at once continued and vigorously prosecuted, and we trust that the Department of Agriculture will find ample means for this research at its disposal out of the funds now available from the appropriations for the new fiscal year.

Under the will of the late Dr. Alonzo Clark, a scholarship was endowed at the College of Physicians and Surgeons, New York, for the promotion of the discovery of new facts in medical science. This scholarship has an annual income of about nine hundred dollars, and the Faculty of the College have worthily bestowed it for a term of three years upon Dr. T. Mitchell Prudden.

Dr. Lewis A. Sayre has recently been elected an honorary member of the St. Petersburg Medical Society. Dr. Sayre's many friends will be gratified to learn that he has returned from a trip to the Hot Springs of North Carolina much improved in health.

Dr. J. F. Hartigan, of Washington, D. C., sailed on the "Belgenland," on July 17th. He is the newly appointed Consul to Trieste, a position which has been described as one of the best of the "travelling scholarships" in the gift of the Government. In some sense this appointment has been regarded as a reward of merit to Dr. Hartigan, his health having been imperiled and impaired during a service done for the Government at Enterprise, Florida, during the epidemic of yellow fever.

Dr. Oscar C. de Wolf has resigned his position as Commissioner of Health of Chicago after thirteen years of intelligent and faithful service. Dr. Wickersham has been appointed his successor.

The Ninth Annual Meeting of the Lehigh Valley Medical Association will be held at Glen Summit, Pa., on Friday, August 16, 1889. The President, Dr. G. N. Best, of Rosemont, N. J., will read a paper on "Evolution in the Causation of Disease," and Dr. Francis X. Dercum, of Philadelphia, will give the Annual Address, and he has chosen for his subject, "Railroad Shock and Its Treatment."

Mr. Jonathan Hutchinson has just been elected President for the ensuing year of the Royal College of Surgeons of England.

AN alleged physician, calling himself "Dr. F. A. Davis, of Johnstown," having sought to work upon the sympathies of the medical profession of New York City, a notice has been issued by Dr. Bryant, of the Department of Health, that no physician of that name has lived at Johnstown, Pa. The impostor may seek to ply his mean fraud elsewhere and we hope he may be caught and punished to the full extent of the law.

SOCIETY PROCEEDINGS.

THIRD CONGRESS OF THE GERMAN SOCIETY OF GYNECOLOGY.

Held at Freiburg, June 12, 13, and 14, 1889.

(Specially reported for THE MEDICAL NEWS.)

DR. KALTENBACH, of Halle, read a paper on

AUTO-INFECTION.

Two causes, he said, produce puerperal infections having as point of departure the genital apparatus. They are produced directly by microörganisms or by intoxication due to toxic matters produced by these same organisms; the microbes penetrate into the tissues, where they reproduce themselves or produce chemical poisons, which pass into the blood. These two powers, infection and intoxication, rarely present themselves in a pure or characteristic form, for more often the pathogenic germs are multiple and mixed with saprophytes or non-pathogenous microbes. Most puerperal diseases are produced by an infection from without, imported by a person, an instrument, or an apparatus. As sources of infection he mentioned especially the cadaver, septic wounds, the lochiæ of diseased women.

The most frequent forms of puerperal fever were formerly divided into septic peritonitis, diphtheria, diffuse phlegmonous inflammation, phlebitis, pyemia, etc. All these numerous forms are considered to-day as having their origin outside of the organism.

By auto-infection is specially meant the infection which arises from the remains of the fœtal membranes, from the necrosis and mortification of tissue which result from the too long compression of the soft parts by the fœtal head, from the putrefaction of the placenta, etc. The streptococcus is more often found as a promotor of puerperal infection and septic peritonitis. The gonococcus is a well-known infectious agent; but besides these, there exist a number of others which it is difficult for us to differentiate, and we have frequent transition between the saprophytes and pathogenic microbes. On the other hand, according to the experiments of Sheffeck and Döderlein, it is difficult to render the vagina aseptic in normal labor; the best prophylaxis consists in making successive disinfections with solutions of corrosive sublimate 1 : 2000 or 1 : 3000.

Out of 1500 labors observed in his clinic, there were but 2 deaths by contamination and 1 by septicæmia; one of these cases was due to a student who had been in a surgical ward where there existed cases of septic disease. 13 per cent. of his delivered patients have presented an elevation of temperature, which would have passed unperceived had the thermometer not been used. These women all were discharged from the clinic on the eleventh day following the labor.

DR. FEHLING, of Basle, considered the expression auto-infection objectionable. For a long time past Pasteur's experiments have demonstrated the important part played by the microörganisms of the air in the fermentation of the urine and milk. How does infection occur? Is it the result of contact; when and under what circumstances does it take place? As causes of these infections, microörganisms have been isolated by Koch, and their special characters studied. Gönner has made, under the direction of Garré, researches on the vaginal secretion of healthy women. He has met with staphylococci and streptococci, but he has been unable to bring about mortal infections in those animals with such germs. Winter has made at Schröder's clinic researches partly on pregnant women, partly on parts obtained from operation, and he has found that in a great many cases the uterus and its neck have no germs on their surface. No microörganism he has found has been able to give a positive result when inoculated in animals.

Döderlein, in his researches on the normal lochiæ, has found that 10 per cent. of women without fever would present microörganisms in their secretions; in one case he found streptococci; the inoculation of pure cultures in animals gave negative results. Tcherniewski, out of eighty-one cases in which he has examined the secretion of delivered women, has met with microbes in one-third of the cases. According to Bumm, no germs can be found in the lochiæ of healthy women.

He had always, in his researches, studied cases in which fever existed. He had found staphylococci and streptococci; in a case of pemphigus in a delivered woman he had found in pemphigoid bullæ a pure culture of streptococci. Grawitz's experiments have demonstrated the possibility of producing pus without staphylococci, simply by chemical irritants; he has even brought on peritonitis in such a way. He had himself observed a case of auto-infection in a delivered woman; when this woman came into his clinic she had a rapid pulse, high temperature, chills, abundant hemorrhage. She died six days after her delivery. At the autopsy he found an abscess of the kidney, with the presence of streptococci in the pus.

DR. BUMM, of Wurzburg, having examined bacteriologically several cases of parametritis, had come to the same conclusion as Fritsch; only one species of parametritis is to be recognized, and that is infectious parametritis. Traumatic parametritis, as usually described, does not exist. The name of traumatic is more often given to exudative parametritis, which, without running into an abscess, finishes by being absorbed, and so escapes histological examination. He had made researches in five cases of exudative parametritis, and had penetrated into the exudate by means of a very fine sterilized canula. In two cases of gonorrhœal parametritis he had found no microörganism, either by microscopical examination, by culture on human serum, or in other nutritive mediums.

He probably had to deal with cases which had existed for a long time; in the three other cases he found streptococci. He had made experimental researches on rabbits, and had succeeded quite easily in producing parametritis by trituration. He had also produced para-

metritis by the direct inoculation of the tissue with streptococci or staphylococci. He did not think that in the normal state one can find pathogenic microbes either in the neck of the uterus or in the vagina; the streptococci found there come from the outside. The staphylococcus aureus, which is a well-marked pathogenic microbe, is easily recognizable, and it is very doubtful whether it has ever been found in the vagina of a healthy woman.

Dr. Leopold, of Dresden, had reduced in his clinic the percentage of delivered patients with fever to three and two per cent., which result is due entirely to antiseptic precautions, and to thorough cleansing of the vagina. Out of five hundred and ten labors, he had had nine cases of fevers oscillating between 101.3° and 102.2°. Of these nine women, more than one was syphilitic, one presented an hæmatoma, another an old exudate, while others had a fœtus in a putrefied state. He had had two cases of death; one he attributed to auto-infection, but on careful inquiry he found that the woman had been infected per vaginam.

Dr. Mermann, of Mannheim, said that out of two hundred and seventy-five labors, which occurred in his clinic, he had observed only five and six per cent. of febrile cases. In all cases he had a temperature below 102°, and the patients left the hospital on the eleventh day. He thought that to restrict the mortality of women in labor, we ought to forbid midwifes to make any irrigations. In Saxony and Hesse there is a regulation forbiding midwifes to make any internal irrigations; they must confine their intervention to the washing of the external parts.

Dr. Kehrer, of Heidelberg, said that we often find microbes in pregnant women. He had himself collected in sterilized tubes secretions from pregnant women, and inoculated these secretions in rabbits, and he obtained in all cases one or more extensive abscesses. He thought that we must employ all possible means of disinfection to attenuate or neutralize the virulence of the germs which could exist in those organs.

Dr. Ziegenspeck, of Munich, said that we sometimes find germs in the vagina, and it is easily conceivable that an auto-infection can produce itself; it would be well to study the path followed by these microörganisms. Dr. Thonen has made researches on seven women who had normal labors; in the lochiæ of these women he had found three times a streptococcus in the vagina, and twice a streptococcus in the lochiæ obtained from the uterus.

Dr. Benckiser, of Karlsruhe, treated a woman who was taken with fever in the fifth month of her pregnancy; this woman had never been examined. As there existed a fetid secretion and, moreover, an elevated temperature, he induced premature labor. The uterine neck was closed. He made irrigations of warm water, and obtained a living fœtus of five months. The placenta was situated in the posterior region, and presented in its lower segment an hemorrhagic portion which had partially undergone decomposition. We had here a true case of auto-infection.

GONORRHŒAL PYOSALPINGITIS.

Dr. Werth, of Kiel, reported a very interesting case of a pyosalpingitis where gonococci were found not only in the pus, but also in the tissue itself of the Fallopian tube. His case was aged thirty-two, a servant, who for five weeks had been complaining of pain in the lower part of the abdomen and renal region. During the last eight days, the pains had become so severe that she was obliged to remain in bed, and had a very high fever. He removed the two tubes without any pus escaping into the abdomen; moreover, he cauterized the pedicle on each side with the thermo-cautery. The patient died four days after the operation, of septic peritonitis. At the post-mortem he found traces of a former peritonitis. The abdominal wound was well closed; no pus was found in the abdomen, the mesenteric glands were hypertrophied, the other organs in an hyperæmic condition. As to the histological examination, he said that before the operation he found no gonococci, either in the uterine neck or in the canal of the urethra. The left tube only contained a single diplococcus, not retained in its cell. Prof. Heller succeeded, however, in staining in the pus from the right tube a number of diplococci contained in the cells of the pus, and also in the tissue of the Fallopian tube. The gonococci were situated in a mass in the epithelial layer of the tube, on a level with the uterine portion, and also in the middle of the organ.

DISINFECTED SPONGES AND CATGUT.

Dr. Benckiser, of Karlsruhe, presented catgut and sponges sterilized at a temperature of 284°. When subjected for twenty minutes to such a temperature they are absolutely sterile. To know whether catgut treated in this manner was sterile, he tried a culture in fifty tubes of agar-agar, maintained at a temperature of 98.3°, and all the tubes remained sterile.

A CASE OF EXTRA-UTERINE PREGNANCY TREATED BY INJECTIONS OF MORPHINE.

Dr. Winckel, of Munich, reported a case of pregnancy of the left tube; the diagnosis had been confirmed by an examination of the uterine mucous membrane, which presented very clearly all the characters of the decidua. At the beginning the sac was the size of a hen's egg. He made an injection of half a grain of morphine into the fœtal sac; the patient remained in bed and had ice placed on her abdomen. At first she felt some pains; at the end of eight days he examined her again and found that the tumor had not diminished in volume. The patient feeling better, wanted to go out; he made a new injection of a quarter of a grain into the fœtal sac, and to-day he finds that the tumor has been largely reduced, although only under treatment for the past four weeks. He had treated nine cases of extra-uterine pregnancy by this method.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, June 17, 1889.

The President, Charles S. Wood, M.D., in the Chair.

Dr. Edward G. Janeway read a paper on

THE DIAGNOSIS AND TREATMENT OF BASEDOW'S DISEASE.

His remarks, he said, were not intended to include the whole range of the disease, upon the main features of which he presumed that all present were sufficiently in-

formed; but from his personal observations in a considerable number of cases he trusted that he might, perhaps, be able to add something of practical interest in the directions indicated in the title announced. When well developed, and presenting all the marked features characteristic of it, Basedow's disease could be at once recognized by any one; but the case was very different in the incipiency of the affection, or when some of the characteristics were rather obscure.

At the beginning the general state of the patient's health was sometimes more apt to strike the physician, and, perhaps, led him to give a wrong name to the malady. Of the three terms most commonly used to conceal the absence of definite knowledge regarding the disease present in more or less obscure cases, neurasthenia, malaria, and lithæmia, the two former were occasionally applied to this disease. As regards neurasthenia, the presence of nervous debility gave some ground for its use, while in other cases the patient not only grew weaker, but had a sense of heat, or even elevation of temperature; thus making the diagnosis of malaria plausible. The adoption of either of these terms, however, was of bad import for the patient, for the reason that the treatment appropriate to these conditions would not subdue Basedow's disease.

Dr. Janeway said he had known even a supposition of phthisis to exist on account of the emaciation, loss of strength, and sense of warmth present, sometimes in connection with a cough due either to an intercurrent cold or to congestion dependent upon enfeeblement of the heart. In such cases the goitre pressed on the larynx and trachea, causing congestion of these parts; while the enlarged heart caused congestion of the lungs, and of itself produced some dulness. Moreover, from these causes, a modification of the respiration occurred, and patients with advanced Basedow's disease had been thought to die of phthisis when none was found at the post-mortem examination.

Each of the three factors of the disease, exophthalmos, goitre, and palpitation, might be used as a designation of disease without having regard to the nature of the process. It was not uncommon for the exophthalmos to be overlooked by the patient and his friends, owing to its gradual supervention. Graefe's diagnostic rule, that the upper lid does not follow the eyeball, as in the normal state, on looking downward, was not a certain criterion, for we might not find it in all cases where slight exophthalmos existed. Moreover, Dr. Janeway had seen it present in one eye and absent in the other. An experienced physician could often detect the exophthalmos when its presence is unexpected; and an excellent test was to ask of old acquaintances who have not seen the patient for some time their conclusion in the case. It was to be remembered, of course, however, that every case of exophthalmos was not dependent upon Basedow's disease.

The enlargement of the thyroid gland might deceive by its presence or mislead by its apparent absence. In the milder cases the slight growth or vascular engorgement of the thyroid (the patient having in the meanwhile grown thinner) might keep the neck of only normal fulness. Attention, however, to the condition of the circulation in the neck would seem to prevent misconception. Even when the thyroid was but little enlarged, the peculiar vascular turgescence, arterial thrill, and arterial and venous murmurs could be made out. Where the thyroid was enlarged, the thrill was particularly noticeable in the inferior thyroid arteries; while when this was not the case, he had felt it rather in the carotids themselves. Basedow's disease had sometimes been mistaken for aneurism, on account of the enlargement, thrill, and accompanying murmurs; and this was particularly apt to be the case when the enlargement was predominantly on one side. An occasional case would present the difficulty of deciding whether the disease was an illustration of parenchymatous goitre accompanied by palpitation or belonged more to Basedow's disease.

The condition of the part might be misleading in several ways. (1) Basedow's disease may complicate organic heart disease of preëxistent date.

(2) At times it becomes difficult to determine whether a murmur of mitral insufficiency is due to an old lesion or is dependent upon muscular incompetence or relative insufficiency of the mitral valve. Dr. Janeway said he had known hearts considerably enlarged so far as the left ventricle was concerned, having well-marked systolic murmurs, audible posteriorly, yield under treatment to such a degree that the murmur disappeared and the heart returned to a nearly normal size. This constituted one of the greatest liabilities in the way of diagnostic error in cases possessed of moderate goitre and exophthalmos, as the tendency was to consider the case one of incurable cardiac disease.

In certain cases to which sufficient attention, he thought, had not been paid, the patient would suddenly fall or have his legs give way under him, but would almost immediately be able to resume the standing position or walk. The question of cerebral or spinal disease might be raised in connection with these; but the rapidity of the occurrence and of its disappearance disproved such a hypothesis. The cases in which he had met with it had been weakened by diarrhœa or vomiting, or as a result of the malnutrition accompanying the disease, and had, under excitement or physical exertion, extremely rapid heart action.

(3) As previously mentioned, the congestion of the lungs from the weakened heart may raise the suspicion of phthisis.

(4) Cases are met with of palpitation without exophthalmos or goitre, but having, as far as the heart and general condition are concerned, phenomena identical with those occurring in exophthalmic goitre. Dr. Janeway said he had been accustomed to consider such cases allied to the disease.

As to the condition of the heart in Basedow's disease, his experience was that cases occur without very marked enlargement. Others, however, were met with in which, with an antecedent history of freedom from cardiac disease, hypertrophy with dilatation is produced by the disease.

Irritable vomiting was at times a very distressing accompaniment of Basedow's disease, and might even be a cause of death.

The treatment, he said, must have relation to the condition of the circulation, to the accompanying anæmia, and to any coëxisting irregularity in the functions of the body, especially menstrual disorder. It was well to remember, however, that menstrual irregularity might be a result rather than a cause of the trouble. One of the most prominent factors in treatment consisted in finding

an agent which will quiet the rapidity of the heart's action. Dr. Janeway's experience has led him to discontinue digitalis in these cases. Formerly, he employed tincture of aconite to considerable extent, and he had seen good results from it in cases where but for the name of the disease he would not have ventured to use it. As a rule, he had the best results from the continued use of small doses.

Of late, however, he had employed the tincture of strophanthus in doses of five minims three times a day, gradually increased if necessary. Of eight cases in which he had used it, he had no information of the result in three; in two a cure had occurred; the only other remedy employed being iron. In one other, complicated with mitral insufficiency and considerable dilated hypertrophy of the left ventricle, there had been a cessation of the palpitation and a considerable improvement in the heart's condition. In the seventh case recovery had occurred, but galvanism was also used. The eighth patient had such irritable vomiting that it was impossible to give the remedy, or even to administer much food, by the mouth, and she succumbed to the exhaustion of the disease and vomiting in a neighboring city, after she had passed from his immediate observation. On the whole, the results from strophanthus had been such that he could add his endorsement to that of others of its utility in this disease. It had succeeded in cases where digitalis had failed, and he preferred it to aconite as less dangerous, particularly in cases where the heart was somewhat enfeebled. He had tried spartein in two cases, but in neither did it prove of much service. In one of these aconite, galvanism, and iron produced a marked improvement.

It was formerly his custom in all cases to advise galvanism, in conjunction with iron and some cardiac remedy, but he had had no case of cure where galvanism was used alone. More recent cases treated by strophanthus and iron had recovered, or improved as rapidly and as thoroughly as the cases in which galvanism was formerly employed, and such results naturally raised the question whether the good results obtained when galvanism was used were not in reality due to the cardiac remedy employed at the same time. Personally, he had not used atropia, though he had seen cases in which it had been used, but without favorable result. Rest, both physical and mental, was a necessary adjuvant in the treatment; as well as the avoidance of worry and of emotional excitement.

It was reasonable to suppose that the condition of the circulation in this disease tended to produce the restlessness, often associated with insomnia, met with in some cases, and in a certain proportion of these it would yield to the ordinary treatment mentioned. In one case he had used sulphonal with good results. Formerly, choice had to be made of the bromides, morphia, or, preferably, codeia, and chloral, or the use of the wet pack or bath. Iron was not invariably necessary, but was usually indicated by the coexisting anæmia. Attention should be paid to the condition of the nutrition, as evidenced by the appetite and general feeling, and by the weight of the body; and whenever this was at fault, appropriate measures should be employed to secure an improvement. In conclusion, he said that confidence on the part of the physician that he could produce an amelioration was of decided benefit. Moreover, it had seemed to him that hospital and dispensary patients were less amenable to treatment than those in the better walks of life. When fright or worry was a prominent factor in the production of the disease, it certainly did not add to the efficacy of the treatment to have a patient surrounded by the sick and dying.

Dr. N. J. Hepburn said that he felt greatly indebted to Dr. Janeway for the practical points which he had given from his rich personal experience. He thought that not infrequently cases are met with in which the ordinary symptoms were absent. Only that day he had seen a case in which the only sign of the disease was a slight enlargement of the thyroid. There was no organic heart disease, but a murmur could be distinguished which was probably anæmic in character. The trouble had lasted about ten months, and very little treatment had been resorted to. The patient's first question was: "Can I get well?" and he thought this was a difficult question to answer. In regard to the treatment, he said he was afraid that we should always be more or less in the dark until the true lesion of exophthalmic goitre was discovered. As to this lesion, it had been supposed that it belonged to the cervical sympathetic. A recent author, in one of the British journals, however, claimed that the trouble was located in the fourth ventricle, and that the cervical sympathetic was perfectly healthy. It seemed possible, however, that there might be some reflex irritation connecting the two lesions. The multiplicity of remedies which had been employed in Basedow's disease, he thought, was an indication of the obscurity of its pathology.

Dr. Alfred T. Carroll said that his experience with this affection had not been very large, but was large enough to teach him that we need not only a better treatment than we now have, but a better clinical history of the disease than any of the text-books give. He thought it probable that there were a certain number of cases which occurred and which were never recognized by the physician as cases of exophthalmic goitre. The circulatory troubles were usually the first to be noticed. In all the cases but one that he had seen, there had been as the starting-point a shock or fright; some sudden disturbance lighting up the train of symptoms which we recognized as constituting exophthalmic goitre. In one case, that of a lady, the trouble was caused by the news of the sudden death of a favorite brother.

Dr. Carroll presented sphygmographic tracings from three cases which recovered; the tracing in one instance being nearly normal, and in the other two showing marked disturbances of the circulation. In the treatment he had derived no benefit from galvanization of the cervical sympathetic formerly so much practised; but he had found veratrum viride of considerable service. He agreed with Dr. Janeway as to the inefficiency of digitalis in this disease.

Dr. J. P. Oberndorfer related a case which he had under observation for about two years. For the first two or three months he employed galvanism alone, but, finding no improvement result, he then abandoned it. Like Dr. Janeway, he saw no benefit derived from digitalis, and the only thing which seemed to do her any good was opium, or, rather, morphia. This retarded the rapidity of the pulse and strengthened its force; but the patient finally died from the exhaustion resulting from an uncontrollable diarrhœa.

THE PRESIDENT said that, as had been mentioned in the paper, in some of the cases the disease abated without any known cause. Some years ago he saw a case of Basedow's disease in which the patient was taken with pneumonia. He was treated with antimony in connection with Dover's powder, and after the pneumonia cleared up the exophthalmic goitre became markedly diminished, and did not increase in severity again.

DR. JANEWAY, in closing the discussion, said that certain points had been brought up by the speakers to which he did not allude in his paper. He said nothing about the pathology because this was so extremely obscure. In some of the cases in which autopsies were made the cervical sympathetic had been found entirely normal, and this would certainly disprove the hypothesis that the lesion of Basedow's disease was located in this portion of the nervous system. More recent investigations would seem to show that the trouble originated, either directly or indirectly, in the medulla oblongata. As to the starting-point of the disease, from a clinical point of view it would not do always to attribute this to such a cause as fright or emotional excitement. In one of the cases reported in the paper, where the patient was a lawyer of distinction, there was no fright, no special anxiety, and no mental strain from overwork. In this instance a complete recovery followed the use of strophanthus and iron. It was a well-demonstrated fact, however, that a great many of the cases do originate from fright, worry, or emotional excitement. Hence, the disease was more common in females than in males; though he had met with a considerable number of cases in men.

He thought it advisable to avoid, if possible, the use of such agents as opium, as sooner or later the nutrition would become affected by the drug, and it was of the highest importance that the nutrition should be maintained as perfect as possible. He had met with cases in which strophanthus and other appropriate remedies produced no benefit as long as the nutrition was interfered with, but when this had become improved the distinctive features of the disease rapidly improved under their use. In neuralgias, also, and all chronic nervous diseases he disliked to use opium for the same reason. There were, however, certain cases of Basedow's disease attended with rapidity of the heart's action in which nothing acted so efficiently in controlling this symptom as opium, and the same was true of some cases of aneurism in the region of the neck.

DR. J. LEWIS SMITH said that all the cases of Basedow's disease which he had met with were in women between the ages of twenty and thirty-five. In one case that he recalled, in which all the characteristic signs of the disease were present, and in so marked a form that the patient's appearance attracted attention on the street, a perfect recovery was secured, principally through the use of aconite.

(To be continued.)

CORRESPONDENCE.

A WINTER VACATION TO THE WINDWARD ISLANDS.

I.

LYING at our very threshold, as we moderns understand distance, there exists a region in which the past of a century seems incorporated into the present as vividly as we could project the picture of some old ruin upon a screen. Here were contributed the first chapters to the wonderful story of our Western World, the home of tradition and the most fascinating romance that so closely borders upon crime. Spaniard, Frenchman, and sturdy Saxon, if at peace elsewhere throughout the world, never met here except in warfare. Here was the school in which England learned to gain and keep the mastery of the sea; where Spanish power was first ground to dust, and French greed lost its grip upon the treasure house of the West. All this and more will be accepted as solemn truth by every boy who has absorbed the literature of the Spanish Main and Windward Islands.

It was not choice but stern necessity that compelled me to look in the direction of the Windward Islands as a health resort, and the fact that my selection proved a wise one, and that I had made the discovery of a new region for the climatic treatment of the chronic catarrhs of our northern winters has led me to offer to the readers of THE NEWS a few letters descriptive of my voyage. "Where are the Windward and Leeward Islands?" was a question that was put to me by nearly everybody who learned of my plans—a question that I answered in a variety of ways. In fact a geographical region that is defined on one side by the direction from which the wind comes, and on the other by whither it blows, has about it a delightful uncertainty that permits considerable latitude of description.

If you are living upon the bank of a river you speak of any place above you as up stream and any place below as down. It is so with the Creole of the Lesser Antilles: all the islands situated to the south of the one he inhabits are "Windward Islands" and those to the north are "Leeward." At the same time, when he travels he goes down the islands by going north from Trinidad, or south if he begins his journey from St. Croix. Let the reader take his map, and, drawing a line south of the islands of St. Croix and St. Bartholomew, he makes all those islands lying to the south the Windward Islands. In this way he groups them geologically; for all, with the exception of Antigua and Barbadoes, are volcanic in origin, while there is no evidence of recent igneous formation in those lying to the north and westward. According to the geographers, however, he must draw his line at Martinique, thence south to Trinidad, they are called the Windward Islands, while those to the eastward of Porto Rica are the Leeward Islands. The description of their place on earth is vague, but why should it not be so since they are as beautiful as some exquisite dream?

It is not in acccordance with good ethical rules to find fault with the ship that brought you safe over, but the truth in the matter may just as well be told once for all. The steamer "Barracouta" was a wet ship. She took water over her bow, and on the slightest chance it would come over her weather side, it percolated through the deck, and from mysterious regions known only to the ship's plumber. She was built, like all steamers that voyage to the Carribean Sea, flat-bottomed and without a keel. Of course she lacked stability, and had a capacity to roll that exceeded belief. Give her a beam sea and she would roll her decks under in good weather. We started out a crowd of sixty, at least ten more than the saloon capacity of the ship, mostly round-trip tourists like

myself. For the first few days we eyed one another coldly and with suspicion after the manner of strangers. But the water melted away our reserve and after we had been thrown into each other's laps sufficiently often we were macerated and shaken down into a very homogeneous and happy family.

After six days we found ourselves one Sunday morning at rest off the town of Frederickstedt, in the Island of St. Croix. A pretty village nestled in its grove of palms. A whitewashed fort, from which floated the Danish flag, frowned at us from the beach. Behind lay the island in a series of receding peaks, clothed in a profusion of tropic verdure. About the low-browed summits hung masses of cloud. From off the shore came a mysterious odor of the tropics, fresh and sweet, a sound of church bells, a restful murmur of surf. I was on shore as soon as I could get breakfast. The houses were low stone buildings, with gardens enclosed in plastered stone walls. Everything appeared very solid, old and well preserved. The interior met all our expectations, as viewed from the deck of the steamer. One beauty after another feasted our eyes in rapid succession. The island is mountainous, sharp cones, with interlying valleys. The rain in the morning left its effects in detached masses of heavy cloud that was hurried along before the stiff northeast trades and produced magical effects of shadows. One mountain apex would stand grand and obscure in its cap of cloud, while a near summit revealed sharply every detail of rock and foliage in the glare of the tropic sun. In the deep valleys the contrasts of light and shade gave immensity and to some winding vistas too profound a depth and gloom for the abode of man, while ever under your gaze in its widest features there would be a burst of sunlight revealing the exuberance of life and foliage. The variety of color that clothed the sides of the mountains and valleys was remarkable. The mango grew in groups with a green as dark as night, the light green of wide stretches of cane-field, and a shade just dark enough for contrast of the graceful palms; the rich red and brown of newly plowed land and the gray and purple of protruding masses of rock. As we gained the summit of a dividing ridge we had a view that equalled anything the earth can produce; not so grand as many, but full of the peace and gentleness that typify nature in her fulness of beauty. A winding valley threading its way amid a procession of mountains that, through their gateways of green, gave a receding vista of glens and valleys in brilliant light and patches of shadow with every color that can grace the earth, ending in a wide expanse of the Carribean Sea, and a sky line that melted into a greenish-purple haze.

It was painful to see amid all these beauties the traces of a Negro insurrection that held the island for three days and left ruined plantations on every side. Some old residents told me that forty or fifty years ago the island was a favorite winter resort of people from the States, bringing with them their horses and carriages. No more exquisite winter climate can be imagined. The temperature does not exceed 80°, always tempered by the northeast trades, and on some of the higher peaks a temperature of 65° or 70° can be found.

We were on board the steamer for six o'clock dinner, and at eight o'clock we weighed anchor and steamed away on our course down the islands.

Ely Van de Warker.

DEATH FROM SULPHONAL.

To the Editor of The Medical News,

Sir: I report the following case of death from sulphonal, which resembles, except in its issue, Case III. reported by Dr. Hay in the July number of the *American Journal of the Medical Sciences*, for in spite of the numerous examples of disagreeable after-effects, it is still constantly recommended as safe in doses exceeding that I gave with fatal result. Kast, in his original report, and other observers have warned against large doses to females on account of especial susceptibility, but I fear that the continual repetition of its safety and freedom from action on pulse, temperature, and respiration, will make others careless as it did myself.

Miss B., aged twenty-eight, American, dressmaker, was thrown from a carriage two years ago. Since then she suffered constantly from irritation of the spine and the symptoms of neurasthenia became marked, but she continued to use the sewing machine as much as her strength would permit. There was no evidence of organic lesion. Neither rest, tonics, nor any form of local treatment caused improvement. She was always very nervous and now had almost constant headache. The excitement of a slander suit decided against her friends caused her to become entirely insane. The type was melancholia, but for a few days hysterical symptoms predominated. The first night she obtained several hours sleep by means of chloral, but her condition was such the next day that I thought the chloral did more harm than the sleep did good, so for several days I simply gave her frequent small doses of cannabis Indica and potassium bromide, pushing her food as much as possible. Some nights she obtained no sleep and sometimes considerable. I then gave her xl ♏ of paraldehyde with no effect at all. Next day she received no medicine and at night I gave her fifteen grains of sulphonal and in one and a quarter hours, patient being still wild and wakeful,she was given fifteen grains more. She soon went to sleep and slept quietly till I saw her twelve hours later. She was then sleeping naturally, and for the next twelve hours she could be easily roused enough to swallow and by energetic stimulation enough to talk rationally, but when let alone would at once be asleep. Pulse 95, respiration but slightly accelerated, pupils normal.

About eighteen hours after taking the sulphonal, the pupils being contracted, $\frac{1}{100}$ grain of atropine was injected hypodermatically and from this on till near her death the pupils were neither unduly contracted nor dilated and responded to light. Aside from the atropine no remedy seemed to have any effect, though in all about $\frac{1}{12}$ of a grain of strychnine was injected, the faradic current, aromatic spirits of ammonia, and later whiskey were freely used.

Her temperature taken about the eighteenth hour was 102°. Leaving her about the twenty-second hour able to answer and strike those who were keeping her awake, I found her on my return an hour afterward apparently dying, greatly cyanosed and scarcely breathing. In trying to keep her up, her head had been allowed to fall forward; I made a complete extension of the head and she began at once to breathe freely. After failure of respiration began, her pulse being good, artificial respiration was kept up for several hours, but finally the

cyanosis began to increase and she died of failure of respiration forty hours after taking the sulphonal.

R. R. Petitt, M.D.

Dayton, Ohio.

NEWS ITEMS.

Report of the United States Board of Inquiry Concerning Epidemic Diseases among Swine.—The Commission, consisting of Drs. E. O. Shakespeare, R. Meade Bolton, and T. J. Burrill, appointed last November by the Commissioner of Agriculture to examine and report upon the causes and means of prevention of hog cholera, have just forwarded the report of their inquiry, which was cut short by the exhaustion of the appropriation at the disposal of the Department for the investigation.

The conclusions of the Commission are as follows:

1. It is the opinion of the Commission, based upon their own individual observations and examinations of the subject, that there are at least two widespread epidemic diseases of hogs in this country which are caused by different microörganisms, but which have a clinical history and pathological lesions more or less similar and very difficult to distinguish without the aid of the microscope and resort to bacteriological methods; and that these two epidemic diseases have been fairly well described in the recent annual reports of the Bureau of Animal Industry, except it does not appear that "hog cholera" of these reports can be said to have its special or exclusive seat in the digestive tract of the animal as distinct from the lungs. So far as the knowledge and the observation of the Commission go, one of these epidemic diseases, viz., that called by the Bureau authorities "swine plague," appears to be far less prevalent than the other which has been named by them "hog cholera."

The Commission are further of the opinion that the disease called by the authorities at Washington "hog cholera" is caused by the specific action of a certain microbe named by them "the hog cholera germ," which has certain characteristics of form, size, movement, mode of growth in artificial cultures, and action upon certain lower animals, and taken together enable one to distinguish it from other microbes which have been described from time to time by various authors as present in swine disease, and that the descriptions of this microbe and its peculiarities, as set forth in recent annual reports of the Bureau of Animal Industry, are fairly accurate.

The Commission are also of the opinion, although to a less positive degree, that the epidemic disease called by the Bureau authorities "swine plague," has as its specific cause a certain microbe possessing characteristics which have been fairly well described in recent annual reports of the Bureau of Animal Industry, which distinguish it both biologically and pathologically from the first-mentioned "germ of hog cholera."

2. It is the opinion of the Commission that the actual and undeniable proof of the pathogenic relations between the so-called "hog cholera" germ, above mentioned, and the disease of hog cholera was first published in the annual report of the Department of Agriculture for 1885, and in the second annual report of the Bureau of Animal Industry of the same year, hence was not antedated with respect to epidemic diseases of swine existing in the United States. The discovery of the disease called "swine plague," and of the microbe to which it is due, must be considered original, on the part of the Bureau authorities, at least as far as work in the United States is concerned.

3. In the opinion of the Commission the epidemic disease of swine investigated by Drs. Billings and Roberts, in Nebraska, however seemingly different in the published descriptions, is identical in its clinical features, pathological lesions and specific cause, with the disease investigated by the Bureau of Animal Industry at Washington, and called by the latter "hog cholera;" and, furthermore, that the pathogenic microbe which is the specific cause of this disease is identical in both instances. It is also their opinion that the descriptions of this germ, published by each of these investigators, are in the main correct. The two chief points in these descriptions upon which the above-mentioned investigators have differed more or less widely, are as to some minor points of morphology and variation of the behavior of the microbe under various methods of staining.

4. It is the opinion of the Commission that the microbe which Dr. Detmers at present regards as the specific cause of "hog cholera" is probably the same microbe which is considered by the Bureau authorities as the specific cause of hog cholera; but, according to present requirements of bacterial research and interpretation, it is impossible to declare that the organism as described by him in his reports, published by the Department of Agriculture, was the same thing.

In their observation of the methods of bacteriological research pursued by the Bureau of Animal Industry at Washington, the Commission are of the opinion that as to carefulness and precision they are up to the standard of modern requirements concerning bacteriological investigations. They are essentially the same as those pursued at Berlin in the Pathological Laboratory of the Imperial Board of Health, and in the Hygenic Institute, of which Professor Koch is the head.

From their observation of the methods of bacteriological research pursued by Dr. Billings, in Nebraska, the Commission are of the opinion that it was difficult, if not inpossible, for that distinguished investigator, by his usual method, to discover and isolate a germ associated with "the hog cholera germ" in the tissues of the body of the pig, and this is particularly true of the so-called "swine plague" germ, claimed by the Bureau authorities to be the specific cause of the epidemic disease latterly named by them "swine plague." In the opinion of the Commission, therefore, the failure of Dr. Billings in his researches to find the so-called "swine plague" germ in the tissues of the spleen (the organ from which he almost invariably made his cultures) cannot be regarded as incontestable proof that the "swine plague" germ has had no existence in the afflicted hogs which have fallen under his observation, and affords no evidence that this last-named disease does not occur in Nebraska.

The Commission regard their experiments concerning immunity as inconclusive and more or less indefinite; yet it seems to be evident that there is a certain degree of protection against artificial acquisition of hog cholera possessed by the Nebraska pigs which had been inoculated and which had recovered from the natural disease, the latter appearing to be slightly less protected than the former. Furthermore, the feeding experiments above mentioned appear to indicate that the hog can be arti-

ficially protected against the action of the virulent living cultures even to a greater degree by introducing the germs into the stomach than by subcutaneous inoculation.

It is the opinion of the Commission that the only proper way to test practically the real value of artificial protection against "hog cholera" is to expose the supposed protected pig to the natural acquisition of the disease under ordinary conditions, such as exist among a herd of hogs suffering from the natural disease. It is a well-known fact brought to light by recent investigations concerning the nature of infectious diseases, that immunity or protection from a second attack, whether artificial or natural, is not absolute, but only relative in degree. There is no known infectious disease, either of man or beast, capable of producing by one attack a degree of protection which is surely and absolutely effective against a second attack.

Experience has abundantly shown that animals which are naturally or artificially protected can be practically overwhelmed by enormous doses of the germs of the disease, and thus be made to suffer a recurrent attack, which may even be fatal. Furthermore, the method of artificial inoculation, and the mode of natural acquisition of the disease, also seem to influence materially the degree of protection acquired. For example, it is well known that Pasteur has put into extensive practical application in France his method of producing artificial immunity against anthrax in sheep and cattle by subcutaneous inoculation, and it is also well known that the losses by this disease among herds where the inoculation has been thus performed has been reduced 90 per cent. as the result of inoculation; yet Koch, as an opponent of Pasteur concerning the practical value of protective inoculation, has demonstrated beyond cavil that cattle in which subcutaneous inoculation has been practised are but little protected against the acquisition of the disease experimentally by way of the digestive apparatus.

It is the opinion of the Commission that disinfection as a general practical means of preventing the enormous annual losses from diseases of swine in this country cannot be made effective under the conditions which exist in the West and other regions where hog raising is extensive.

As far as our present knowledge extends treatment of existing cases is utterly futile. There remain, therefore, to be considered but two alternative means of prevention—quarantine and extermination of infected hogs, with their surroundings, or on the other hand, some form of preventive inoculation.

The vast importance of the subject calls for an exhaustive investigation as early as possible of this latter means, for the former is very difficult of application.

Some of the tests made in Nebraska under the direction of Dr. Billings certainly give promise of great possibilities in this direction. It is the opinion of the Commission, however, that an attempt to produce immunity from "hog cholera" artificially by the use of the living germs of the disease, either through the stomach or through hypodermic inoculation is very objectionable, and involves a serious risk of more widely extending the disease and increasing rather than diminishing the already enormous losses therefrom. For every hog thus treated becomes, for a time at least, a centre of infection from which an epidemic may directly or indirectly spread widely. Furthermore, the use of the living germs seems, at least in many instances, to stunt permanently the growth of the pig. Experience acquired in recent years shows that the chemical products of certain disease-producing germs in artificial cultures possess the same power to create immunity as do the living germs themselves; and some incomplete experiments performed by ourselves and others seem to indicate strongly that the chemical products of the "hog cholera" germ in artificial cultures also possess a similar power.

If further investigation shall prove this to be an indisputable fact, then, in our opinion, a safe, harmless, efficient, and extremely practical means of preventing "hog cholera" free from any risk of thereby extending the disease and continuing the enormous losses at present suffered by our countrymen will soon follow.

We have reason to believe that the threshold of such an important discovery has already been crossed; and we, therefore, earnestly advise that thorough and exhaustive investigations be as rapidly as possible made in this direction, and without stint of money or hampering limitations of time.

The Sale of Tuberculous Flesh and Milk.—The *British Medical Journal* of July 6th, says that the Scottish Veterinary Association, at a recent meeting in Edinburgh, considered a motion submitted by Prof. W. O. Williams, "That the Society thoroughly believing that tuberculosis is a contagious disease, urge upon the Government—first, to stop the sale of milk from animals suspected of being infected; secondly, to suppress the consumption of meat from tubercular animals; and, thirdly, to give compensation for a limited number of years." In the discussion of this motion it was apparent that though there were differences of opinion as to how much of an affected animal ought to be condemned as unfit for food, all the speakers were in favor of visibly diseased parts being destroyed, and were of opinion that the milk from diseased animals was especially dangerous. They were also unanimously in favor of legislation to stamp out the disease, to secure proper inspection at abbatoirs, and moderate compensation to owners. A committee was appointed to draw up a memorial to Government to secure these objects and to take action in the matter with other societies.

Natural Purification of Polluted Streams.—The growing population of the many cities which discharge their sewage into rivers gives increasing importance to the question how great a degree of pollution is allowable in a stream of given flow, the water of which is to be used lower down for domestic or for manufacturing purposes. Mr. Rudolph Hering says that oxidation and decomposition of sewage matter were for a long time thought to be the main cause for the clarification of polluted rivers. To-day it is known to be but a minor cause compared with dilution and subsidence; and if the sewage is discharged in a fresh condition into a stream of water, its destruction is in part due to fish and other aquatic animals. Some of the refuse from stock-yards is disposed of, no doubt, in this way. Most of the decomposition, or oxidation as it is usually termed, of sewage is effected by the myriads of microscopic plants, microbes, or bacteria contained in both air and water, which at once seize upon dead organic matter. For purifying the

sewage discharged into a river, oxidation can be depended upon only to a limited extent, because of the comparative slowness with which it takes place. Subsidence of the heavier matter tends to clarify it before it flows many miles; dilution with a sufficient quantity of clean water prevents an offensiveness almost at once; but oxidation requires many days under continuous aëration of the river. From a comparison of data in regard to the actual purification of polluted streams we may draw the following inference: Rivers not to be used for water-supplies, but to be inoffensive to communities residing a few miles below, to remain fit for ordinary manufacturing purposes, and to sustain the life of fish, may receive the sewage from one thousand persons for at least every one hundred and fifty to two hundred cubic feet of minimum flow per minute, supposing that natural subsidence of the heavier matter takes place immediately below the town discharging the sewage. Beyond the above limit it appears to be advisable to resort to land or other filtration, or to chemical precipitation. — *Popular Science Monthly*, April, 1889.

A Royal Ophthalmologist.—H. R. H. DUKE CHARLES, M.D., of Bavaria, continues in the Bavarian Tyrol the philanthrophic practice of ophthalmic surgery, to which he devotes the spring months in the Austrian Tyrol. On the 3d instant, at the Tegern See, he performed with complete success his one-thousandth operation for cataract. For the occasion, which was a festive one, the surgical theatre was decorated with flowers by the sisters of the hospital, of which his Royal Highness is the patron and working president.—*Lancet*, July 13, 1889.

In Memory of Dr. James B. Hunter.—The New York Obstetrical Society has adopted the following resolutions on the death of Dr. James B. Hunter:

Whereas it has pleased Almighty God in his infinite wisdom to remove from our midst our friend and colleague, Dr. James Bradbridge Hunter, in the prime of his life and in the morning of his usefulness, therefore be it

Resolved, That, while we bow in submission before His supreme will, we recognize in His fiat the loss of one beloved and honored by us all for his gentle virtues and manly qualities, of one who will long be regretted, and whose place will forever remain unfilled amongst us.

Resolved, That, in his removal the entire profession of medicine in America suffers a loss which cannot fail to be appreciated by all connected with it.

Resolved, That the kind sympathy of this Society, for which he has done so much, and its sincere condolence be tendered to his bereaved family; and that it cause a copy of these resolutions to be spread upon its minutes, published in several of the daily and medical journals of the city, and transmitted to his immediate relatives.

Corrigendum.

To the Editor of THE MEDICAL NEWS,

SIR: Permit me to correct an erroneous phrase in the report of my paper read at the recent meeting of the American Otological Society, as published in your issue of July 27th. It reads: "Contesting the view that any colobomatous opening in the flaccid membrane *was* wholly negatived by modern embryologists;" whereas it should be: "Contesting the view . . . *as* wholly negatived." The change is slight, but it wholly perverts the cardinal meaning of my paper, which is essentially a protest against the assumption that the "foramen of Rivinius" is anything else than a pathological perforation.

Very respectfully yours, B. ALEX. RANDALL.

1806 CHESTNUT ST, PHILADA., August 5, 1889

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JULY 30 TO AUGUST 5, 1889.

By direction of the Acting Secretary of War, leave of absence for seven days is granted ANDREW K. SMITH, *Colonel and Surgeon.*—Par. 12, *S. O. 178, A. G. O.*, August 3, 1889.

HALL, WILLIAM R., *Captain and Assistant Surgeon.*—Leave of absence for ten days is granted.—Par. 5. *S. O. 60, Headquarters Department of Dakota*, July 27, 1889.

ROBINSON, SAMUEL Q., *Captain and Assistant Surgeon.*—The leave of absence for two weeks, granted by Par. 11, S. O. 165, from these headquarters, is hereby extended ten days.—Par. 8, *S. O. 272, Headquarters Division of the Atlantic*, July 30, 1889.

MAUS, LOUIS M., *Captain and Assistant Surgeon* (Fort Porter, New York).—Leave of absence for twenty days, on surgeon's certificate of disability, is hereby granted.—Par. 2, *S. O. 273, Headquarters Division of the Atlantic*, August 1, 1889.

By direction of the Secretary of War, so much of Par. 1, S. O. 159, A. G. O., July 12, 1889, as directs LOUIS BRECHEMIN, *Captain and Assistant Surgeon*, to return to his station at the close of the encampment of the Illinois National Guard, is amended to direct him to report in person, not later than August 20, 1889, at Fort Robinson, Nebraska, for duty at that place.—*S. O. 174, Headquarters of the Army, Adjutant General's Office, Washington*, July 30, 1889.

HARRIS, H. S. T., *First Lieutenant and Assistant Surgeon.*—The leave of absence granted in S. O. 140, A. G. O., June 18, 1889, is further extended two months.—Par. 9, *S. O. 176, A. G. O.*, August 1, 1889.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING AUGUST 3, 1889.

BRYANT, P. H., *Assistant Surgeon.*—Ordered to temporary duty on iron clads, Richmond, Virginia.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FROM JULY 20, TO AUGUST 3, 1889.

HUTTON, W. H. H., *Surgeon.*—When relieved at Mobile, Alabama, to assume command of the Service at Baltimore, Maryland, July 23, 1889.

PURVIANCE, GEORGE, *Surgeon.*—When relieved at Baltimore, Maryland, to assume command of the Service at Philadelphia, Pa., July 24, 1889.

GASSAWAY, J. M., *Surgeon.*—Ordered to New Orleans, La., for temporary duty, August 2, 1889.

GOLDSBOROUGH, C. B., *Surgeon* —Granted leave of absence for thirty days, July 29, 1889.

VAUGHAN, G. T., *Assistant Surgeon.*—Orders to Norfolk, Va. revoked; to proceed to Cairo, Illinois, for temporary duty, August 1, 1889.

GROENEVELT, J. F., *Assistant Surgeon.*—Relieved from duty at Gulf Quarantine Station; ordered to Mobile, Alabama, for temporary duty, August 3, 1889.

ORIGINAL ARTICLES.

PRELIMINARY OBSERVATIONS ON THE BACTERIA IN ICE FROM LAKE MENDOTA, MADISON, WIS.

BY H. L. RUSSELL, B.S.,
OF POYNETTE, WISCONSIN.

DURING the winter of '88 and '89 experiments were conducted in the Bacteriological Laboratory of the University of Wisconsin to test the purity of the ice-supply used in the city of Madison, and also to repeat some observations, which had been made by previous observers, concerning bacteria in ice. The importance of the bacterial analysis of water has been well recognized, by the amount of care and attention which has been bestowed upon it. In the investigations carried on by the different boards of health, the biological as well as the chemical analyses are made to aid each other in determining the potability of water. Less labor has been bestowed upon ice; yet it is no less important. Ice has now come to be used in so many different ways that it is as necessary we should be supplied with that which is as pure as possible, as it is that our water-supply should be pure and wholesome. Our water-supply might be ever so good, but if we introduce into it an impure ice we run a risk as great as if the water itself was contaminated.

The popular notion, that water entirely purifies itself in freezing, not only with respect to its dead organic matter, but also as regards its living animal and vegetable forms, has been proved to be fallacious so many times, that it would seem to be a waste of time to recount the methods and results involved.

The problems connected with biological analysis are often many and difficult. Beside the extreme care which must be maintained throughout the whole work, the results obtained must be interpreted in a proper manner before they become of any practical value. To the popular mind, the word bacteria is closely associated with the idea of disease, so that when we find large numbers of these organisms in water we naturally look upon it with suspicion, but such is not necessarily the case. By far the larger majority of these microbes which we find in the earth, air, and water are perfectly harmless. They are saprophytes rather than parasites.

In water we find a group of these bacteria which are apparently indigenous to this medium. They grow and thrive better here than in any other culture. These "water bacteria," as they are called, play no *rôle*, as far as is known, in producing disease. In addition to these innocuous forms there are numbers of species of pathogenic germs, which are able to thrive, or, at least, exist, in water for a considerable time. The testimony of various observers is quite contradictory as to their ability to grow, especially in reference to the specific germs which cause cholera, typhoid, and anthrax. But the tracing of numerous epidemics of some of these diseases to contamination from water shows that great care should be taken in determining whether the water-supply affords any opportunity for the transmission of disease germs. The most common way for the introduction of these germs into the water systems of cities is where the supply is in any way subject to sewage contamination. This is particularly dangerous, as examination of water at any particular time may fail to reveal the specific germ of the disease, but the occurrence of one or two cases and the emptying of any dejecta, or any other contaminated material, into the sewer system may be sufficient to contaminate what before might have been regarded, by analysis, as pure water.

The water-supply of this city, being derived from deep artesian wells, affords very little chance for contamination. Examinations made from samples taken from delivery faucets of the water mains of the city gave on an average less than thirty germs per c.c., and all of them recognizable as harmless water forms. But in the case of our ice-supply, at first sight, safety is not so assured. The supply which is used in the city and that which is largely shipped to surrounding towns throughout the State, are taken from Lakes Monona and Mendota. From Mendota is taken the ice used for home consumption, and from this source was obtained all the samples which were examined. This lake is about six miles long, by four or five broad, and in many places is about one hundred feet deep. Monona is considerably smaller and much shallower. These two lakes receive all the filth and waste of a city of thirteen thousand inhabitants, Mendota receiving in addition the sewage material from the Wisconsin State Hospital for Insane.

The ice-supply of the city was subjected to quite an exhaustive analysis, to see if it was in any way subject to sewage contamination, and also to investigate several other problems in connection with bac-

teria in their relation to ice. Our inability to determine, ordinarily, whether bacteria in ice or water are pathogenic or not, would make a rule based on the numerical content of the water important, if such could be the case; but unfortunately this we cannot do with any degree of safety. Fränkel states that water containing more than fifty germs per c.c. should be subjected to some process of filtration;[1] but this is purely an arbitrary rule. A sample of water might contain only a few germs in which pathogenic germs were abundant, yet this water would be manifestly more dangerous than one which might contain a far greater number of the ordinary water forms. However, in the absence of a numerical rule we have still a method that may indicate the sought-for result. Where we find two or three, or, at most, only a comparatively few species of germs, we may quite safely assert that the water is practically free from sewage; but where a large number of different species are present it shows the possibility of contamination by foreign ingredients. The prevalent water bacteria are so universally present that most of them can be identified with comparative ease.

The observations upon ice were conducted in the following manner: From the interior of a large block of ice were taken several small pieces, which were washed in a stream of hot water, the temperature of which varied from 75° to 90° C., then rinsed in distilled water and placed in sterilized chambers. The ice was then melted, and before it was completely melted samples of it were drawn off by sterilized pipettes and mixed with meat-peptone gelatine and prepared according to Koch's well-known method. Three or four plates were made from each sample, so as to get the average of as many as possible. The plates were counted after two or three days' growth. No definite time could be taken, on account of the variation in rapidity of growth of colonies. They were allowed to grow as long as possible, the development of the liquefying colonies being checked by the addition of a drop of ferric chloride. It was found, by diluting some of the plates considerably with sterilized distilled water, and counting them daily from the first appearance of the colonies until they could no longer be separated, that the number of colonies increased about ten per cent. a day for three or four days. This makes quite a difference in the number of germs present and is probably caused by the wide variation in age and vitality of the germs.

Comparisons between lake water and freshly frozen ice.—Comparisons were made with the view of determining how much the bacterial content of the water was diminished by freezing. The ice used in the experiment came, in all cases, from the lowest layer, which was formed after February 18th. About this time a large body of ice was removed for the ice houses, and on this date came on a cold spell which lasted for quite a number of days, so that the ice was formed very quickly, and was very clear and transparent. Samples of ice used for this experiment were in no case frozen for more than five or six days. The aggregate results of this comparison are only indicated here:

Twenty-seven samples from lake water averaged 683⅔ germs per c.c.; thirty-five samples from freshly frozen ice averaged 270⅓ germs per c.c. The average number of germs per c.c. for each set of plates varied, in the case of ice, from 14 to 1249; in the case of water, from 3 to 3167.

According to these figures, only about sixty per cent. of the bacterial content was lost by freezing. Prudden claims that ninety per cent. are thus destroyed.[1] Fränkel has shown, however, that while in some cases the loss may reach as high as ninety per cent., ordinarily it is much less.[2] The variation in number of germs which occurs in different strata of the water is probably the cause of this wide variation, and the fact that different species are differently affected by freezing, makes the relation difficult to determine, except for each case.

Snow ice versus clear ice.—The popular belief is held that snow ice contains more impurities than transparent ice. This is, no doubt, due to the fact that we can detect any visible impurities much sooner in clear ice than in an opaque block. To see if this popular notion rested upon any basis of truth, experiments were made with snow and clear, transparent ice. One might quite naturally expect to find the snow layer well filled with air bacteria, as well as water forms which have welled up through the cracks in the ice, but such in our experiments was not the case.

Cultures made from freshly fallen snow, and from that which had lain on the ground for a considerable length of time, almost always contained quite a number of species of bacteria, while the snow ice, as a rule, contained only those species which were found in clear ice. This fact shows that air bacteria do not stand freezing in water as well as the indigenous water forms. Quite a large number of comparisons were made between clear, transparent ice and snow ice.

The following table indicates only in a general way the results obtained. The percentages give a fairer estimate for comparison than the figures themselves, but the evidence is not so overwhelming on either side as to settle the question decidedly.

[1] Arch. f. Hyg, Bd. i. S. 302.

[1] Med. Record, vol. xxxi. p. 344.
Zeit. f. Hyg., Bd. i. S. 308.

TABLE SHOWING RELATION BETWEEN

Clear Ice, 114 samples.		Snow Ice, 39 samples.	
No. of germs per c. c		No. of germs per c. c.	
Less than 10	15 per c		
Between 10 and 50	32.5 "		
" 50 " 100	10+ "	Less than 100	36 per ct.
" 100 " 200	12+ "	Between 100 and 200	20 "
" 200 " 1000	13+ "	" 200 " 1000	36 "
" 1000 " 5000	7+ "	" 1000 " 5000	5 "
5000 and upward	9 "	5000 and upward	2½ "

The local variation of the number of germs detracts from the value of these observations, but where as large a number of samples are taken as were secured in the above case, this element of error ought to be largely diminished. To overcome this as much as possible, samples were taken from contiguous parts of the same block with the following results:

TABLE SHOWING RELATIVE NUMBER OF BACTERIA PER C. C. FROM ADJACENT PORTIONS OF SAME BLOCK.

Snow Ice, 18 samples.	Transparent Ice, 17 samples.
31	192
497	14
115	80
395	6924

Numbers given are the total averages made per c.c. from each set of plates.

Numbers on horizontal line indicate the number found in adjacent portions of the same block.

Here we have as favorable conditions as it is possible to secure, and yet we can establish no definite relation. This variation, and particularly an excessive number, which is occasionally found, is due to the collecting of certain forms into gelatinous zoöglœæ, which dissolve with difficulty in water. Only by thorough shaking of the melted gelatine, with which the water is mixed, can this mass be separated, and the individual germs develop as single colonies in place of one large colony.

Influence of continued freezing upon bacteria.—Comparisons between the upper and lower surfaces of clear ice were made to see if any definite difference existed between ice which had been frozen for a longer period of time and ice just formed. Only samples taken from the upper and lower surfaces of the same block were used for this experiment.

TABLE SHOWING NUMBER OF GERMS PER C. C. IN CLEAR ICE.

From bottom, 32 samples.	From surface, 32 samples.
20	80
355	54
1249	618
71	163
13	10
14	9
141	763
Total aver. per c. c. 266	244

The conditions under which this ice was secured were such that the date of formation could be definitely ascertained, and all samples used were very clear and transparent. If continued freezing acts detrimentally on the bacteria incased in the ice, then the analyses of the upper layers of the ice, taken at different stages of the season, should show a slow but steady diminution in their germ contents. The following table indicates the number of germs per c.c. found in a clear, transparent layer just beneath the surface. The ice was frozen February 18th, and cultures were made from February 23d till March 14th, at varying intervals.

TABLE SHOWING NUMBER OF GERMS PER C. C. FOUND IN SAMPLES OF ICE THAT WERE FROZEN FOR DIFFERENT PERIODS.

	Number per c. c.	Days frozen.
February 23	95	5
March 1	763	11
" 2	20	12
" 8	7	18
" 11	149	21
" 12	10	22
" 14	40	24

Here again the results are so contradictory as to show that by analysis of natural ice no definite proportion can be established. The only way possible to secure definite results is to freeze water containing a known number of bacteria; yet, in this way the objection can be well urged, that we are not complying with natural conditions. If we take a fresh culture of some specific germ, and dilute it, and then freeze it, we will have the vitality of the individual cells much more nearly equal than exists in nature, even within the limits of a species, not to say a number of species.

Influence of freezing on different species of water bacteria.—With the two forms which were the most common in water and in ice, one of which is non-liquefying and the other a liquefying bacillus, the following observations were noted to see which was affected the most by freezing. Only the proportions existing between these two forms are given in the table.

PROPORTION EXISTING BETWEEN THE TWO SPECIES

IN WATER WAS			IN ICE WAS		
Non-liquefying bacillus.		Liquefying bacillus.	Non-liquefying bacillus.		Liquefying bacillus.
5/6	:	1	3.5	:	1
15	:	1	9	:	1
8	:	1	7.5	:	1
30	:	1	3.2	:	1
7.5	:	1	1.5	:	1
13.5	:	1	5.6	:	1
100	:	1	2.5	:	1
			18	:	1
			13	:	1
26		1	7		1

In every case but one the number of non-liquefying germs was greater than the liquefiers, and it was found that the proportion between the two species was much less before freezing than after.

Bacteria in snow.—In order to see if the bacteria of snow were similar to those found in ice, cultures were made from snow at different times. The number of species found in snow always exceeded the number found in ice, but the number of germs was generally much less, unless snow was taken which had lain quite a while upon the ground.

Samples were also taken from snow collected about six hours after the storm had begun, and also at its close, after twelve hours' duration.

Number of germs per c.c. (eight samples):

After 6 hours' duration . . . 6, 12, 3, 6; average, 7.
" 12 " " . . . 4, 6, 2, 0; " 3.

This indicates that the snow purifies the air of its germs to a large extent, and that at the close of a long storm the atmosphere may be practically devoid of germs.[1] These experiments were conducted in the neighborhood of inhabited buildings, so that the meagreness of germs is still more striking. No regular increase was found in old snow, although, as a rule, it contained a larger number of germs than did freshly fallen snow. In the cultures from snow a large number of moulds and oïdiums also developed, showing that these germs are very prevalent even in our winter air. Only occasionally did germs of this kind develop in cultures made from ice or water.

Relation to disease.—In the analysis of any considerable number of samples of ice one would naturally expect to find quite a large number of species present, but in these analyses such was not the case. By far the larger number of germs found were included in three species, and two of these furnished the major portion of the whole number. This applied not only to analyses made from Madison ice, but from ice taken from several different places throughout the State. Occasionally other saprophytic forms were found, but in only a few cases were any germs found that could be suspected of sewage origin. The colonies found in these cases were identical with those isolated from ice from the Milwaukee River, at Milwaukee, Wis., where it was known to be contaminated with sewage. This form was not pathogenic in its characteristics, but it shows a possibility of sewage contamination, and where such is the case safety is not absolute. As long as typhoid cases are unknown we might not suffer any danger from the use of this ice, but the introduction of contaminated material from one or two cases might be sufficient to produce the disease in an epidemic form. The two or three most prevalent forms were worked out and grown in various culture media. Their physiological characteristics, as far as they were tried, did not give any results indicative of pathogenic qualities. Their characteristics upon various culture media are not detailed here, as they probably belong to some described species, although they were not identified.

Briefly summing up the results which were obtained, they may be stated as follows:

1. No evidence of any species of pathogenic germs were found, although slight evidences of sewage contamination were present. Our inability to distinguish pathogenic from non-pathogenic germs, except by special differential cultures, leads us to lay considerable stress upon sewage contamination. Where traces of this are present, danger to a greater or less degree exists. The comparative absence of typhoid cases in this city for the past season would have made a special search for the specific germ probably fruitless. All the different forms isolated during the progress of the experiments were investigated with this point in view, but none of them yielded any results indicating the presence of the typhoid germ in the ice.

2. In testing the effect of freezing upon bacteria no very accurate relation is possible to be made. From the sixty-two cultures made for this experiment it was found that the bacteria in ice had decreased about sixty per cent. as compared with the number found in the water. This proportion is not constant and may range somewhat higher. In a general way it might be stated that from fifty to ninety-five per cent. of the germs present in the water are destroyed by freezing. The influence of continued freezing of the germs cannot be determined by analysis of natural ice. The variation in the number of germs present in different parts of the same block is so great that it is practically impossible to establish any relation between them. Even pieces of ice taken from the same block at the distance of only a few centimetres apart gave widely differing numbers of germs. This element of error is so large that it practically eliminates the use of natural ice for the determination of any of these problems, unless a very great number of observations are made. Of the two most prevalent forms found in either ice or water, the non-liquefying bacillus suffers much greater loss by freezing than the liquefying species.

3. To determine a proportion between snow and transparent ice, as regards their bacterial content, over one hundred and fifty analyses were made. It was found that the transparent ice, as a rule, contained less than the snow ice, but a larger number of germs per c.c. were found in clear, transparent ice in several cases than was found in any sample of snow ice. Here again this local variation prevents

[1] To prove this conclusively one would have to resort to analyses of air to determine the number of germs present in the air itself after the storm.

any relation being established between these two kinds of ice.

4. A number of different forms of bacteria were isolated from snow, in addition to several different species of moulds and oïdiums. The number of germs found was quite small, there being the least number present in snow which was collected at the close of a continued storm. Snow which had lain upon the ground for a length of time yielded a large number. These were deposited upon the snow from the air.

THE PSYCHOLOGICAL FACTOR IN SELECTING A CLIMATE FOR INVALIDS.[1]

By EDWARD O. OTIS, A.B., M.D.,
of Boston.

"There is between the condition of the mind and that of the body," says a modern novelist, "an inter-dependence which cannot but be recognized by every physician." Recognize this fact we do, but I am inclined to think that we give less practical weight to it in our treatment of disease than we ought or might with profit to our patients. To adapt best the remedy, be it climatic or medicinal, to the case in hand, the psychological side of the question, as well as the physiological and pathological, must have its due consideration. Mental influences produce an infinite variety of bodily effects, from an anorexia to a *de novo* phthisis, insanity, or death even. In such a serious matter, then, as a change of climate for a less or a greater period, involving frequently a breaking-up of social and family ties, much more careful attention, it seems to me, should be given to the mental peculiarities and bias of the patient than often, apparently, seems to be the case.

If the *sana mens in sano corpore* is capable of infinite variations, how much more marked are the vagaries of the mind disturbed from its equipoise by the perturbing influences of bodily disease. How often this is illustrated in phthisis we all know. Peculiarities hardly noticeable in health are exaggerated in disease. Every person when sick is more or less of a child, as most of us from personal experience have realized, often to our surprise and chagrin. From a psychological point of view, then, we ought, it seems to me, to consider various factors when a change of climate is contemplated for an invalid, whatever the malady may be. In a general way they are these: *First.* The temperament or mental disposition. Is the patient naturally buoyant and happy, or, on the contrary, often depressed and inclined to take a Mantilinian view of life? *Second.* Previous habits and mode of life. Has the patient been active, fond of society, used to much excitement and frequent change; or lived a quiet, equable life, like the peaceful one of the country? *Third.* The amount of physical activity to which the patient has been accustomed. Has he led more or less of an outdoor life; does he have a fad in shooting, fishing, and the like; or is he of sedentary habits, devoted to books, art, or what not? *Fourth.* The matter of domestic ties. In the contemplated change will the invalid be compelled to sever close ties of relationship—a wife to be separated from her husband, a child from its parents, a mother from her children, etc.? *Fifth.* Is the patient to be placed in an environment of invalidism, where he will have his malady suggested to him continually, by seeing others sick and dying with it about him? *Sixth.* The age of the individual.

That it is important to consider all these elements, in selecting a climate for those patients whom we advise to change their skies, is obvious enough, I think; for that climate is the ideal one for the case in hand which best is adapted to his especial needs and conditions, even if it does not possess all the elements of an intrinsically ideal climate. Better a little less altitude and an agreeable environment; or more moisture, with an opportunity of indulging in one's pet hobby; provided always that the point yielded in the climatic conditions is counterbalanced by the point gained in mental contentment.

An analysis of that bundle of peculiarities which constitutes what we call one's temperament is no easy matter, and still, it seems that it ought to have careful study when a change of climate is under advisement. Here, for instance, is an individual who is a veritable melancholy Jaques, always thinking that the days are waxing evil and he with them, who has a "melancholy of his own, compounded of many simples, extracted from many objects." In ordinary health it requires the combined efforts of his friends and family to keep him in tolerable spirits. Once let him fall sick and he apprehends a speedy dissolution. Such a man is an unfortunate patient to deal with under any circumstances. When the matter, however, of climate comes up we should rather send him to a place of varied interests and attractions to divert and amuse him as much as possible, than to a Colorado ranche or an Adirondack village in winter. Another person, on the contrary, possesses one of those happy, sunny dispositions capable of extracting pleasure from all the little incidents of daily life. Such a one will content himself almost anywhere; and to whatsoever climate you decree him, there he will find a tolerable amount of contentment and happiness. When once he has conquered his nostalgia, you can venture to send him to such places as you would not dare to suggest to the former man.

Between these two extremes we have every variety of disposition or mental attitude, either natural or as

[1] Read before the American Climatological Society, June 24, 1889.

a result of the malady. Of course, it is a delicate question and one requiring much consideration how much weight we should give to this factor in our decision. The nervous, excitable person is often best consigned to a quiet, restful place, and the contrary is often best for one of phlegmatic nature, for to give him an interest in something may be the most important step toward his recovery.

One's natural disposition, to a great extent, shapes his way of life and determines his habits. Environment and intercurrent circumstances, however, are important elements, as we know, in the matter. We have only to consider, however, the mode of life as it exists when the patient comes to us, and to settle the amount of its influence in determining the kind of place and climate best for him. We are all creatures of habit, and so strongly and firmly bound by it, and yet so unconsciously, that we only realize it when we attempt to change or break the chain. Take the most familiar illustration, a business man accustomed for years to a daily routine in a city. Resources outside of his business he may have few or none—no hobby or favorite outdoor amusement. Send him away to a lonely place, or to any place, indeed, and he is wretched, the habit of his life is broken, and he realizes how strongly he was bound by it. If, however, it is possible to place him in a sufficiently favorable climate for his disease, and at the same time allow him to continue to some extent in the way of his former life—if, also, the malady permits it—for instance, sending a phthisical merchant to Denver, El Paso, Los Angeles, or where you please, and there indulge him in the semblance at least of following his former occupation, then, it seems to me, we supplement greatly the beneficial effects of the climate by the contentment of mind the continuance of his former habits of life gives.

Or, again, take a young woman, city bred and accustomed to much variety of life in the way of amusements and social diversion. It may be the wisest plan to send her to a place with an environment the reverse of all this, where the life is the simplest and most peaceful conceivable, like that of a western ranch or a small southern village. Assuredly it will be if she is suffering from neurasthenia. It may be, however, that to continue a limited amount of the old excitement, if I may so term it, may keep her in better mental equipoise than suddenly cutting it all off. Denver, St. Augustine, Fortress Monroe, Cairo, the Riviera, may be more curative for her than the quiet, isolated life of a mountain hamlet or a New Mexico ranch.

The tastes of a patient play a not insignificant *rôle* in his physical condition and well-being, and a disregard of them may vitiate the good results hoped for by the climatic change. Here, for example, is a person devoted to music; it may be that this very devotion is the cause of the phthisis or neurasthenia. Deprive him, however, of all opportunity of hearing a sonata or a symphony now and then, and he is wretched. Send him, on the contrary, to a resort like Colorado Springs, for instance, where he can gratify his taste occasionally, and in addition allow him his piano, with proper restrictions, and he will be happy, and far more readily and quickly adapt himself to the new and changed conditions.

Or, another is a botanist *con amore*. For him a place with a large and varied flora, such, for instance, as some portion of the Rocky Mountains or Southern California, will be more attractive and consequently more beneficial than a sea voyage or Davos. And so, in brief, by studying the tastes and inclinations of the invalid to be exiled, as good a climate may be chosen and in addition a point gained by the greater contentment the favorite occupation or amusement affords.

Here I will digress long enough to say that for these reasons, as well as others more directly climatic, it seems to me that it is of the greatest advantage for the physician, who frequently has to advise his patients where to go for a different climate, to have visited as many of the resorts as possible. He may not, probably will not, remain long enough to make any extended study of the climate itself. This has generally been done by the resident physicians, but he will—which will be of great value to himself and his clients—have found out the resources of the place, its attractions, amusements, the class of people his patients will be thrown with, and all the little data and detail as important in their way as the purely climatic side of the question.

The matter of length of residence in the climate selected depends on many considerations, principally on the kind, character, and extent of the disease. I shall only touch upon this subject here in so far as it relates to the psychological element involved. In maintaining a healthy mental equilibrium, so far as this is possible with an invalid, the diversion of change is a powerful factor. Some physician has said—I have forgotten who, that the invalid should change his residence every month, and there is much of truth in the saying. Now, within the area of prescribed climate a frequent change can often be attained. For instance, a patient who has had selected for him the climate of eastern Colorado, can change Colorado Springs for Santa Fé for a little time in the winter, and in the summer go up to the Estes Park or some of the many other mountain resorts, breathing all the time the same kind of air. Or, again, one who has had prescribed for him a mild sea air may vary the localities where he finds it. St. Augustine, Fortress Monroe, Santa Barbara, or a sea

voyage about the West Indies, all afford him his specific climate with the diversion of change and variety of scene. Moreover, these changes can frequently be made within a limited area, and with no great exhaustion from lengthy journeys, or large expense.

The manner of life as to physical activity is another and important factor, looked at from a psychological standpoint, in the selection of a place for one's patient from amongst those climatically proper for the case in hand. Some individuals will be active as long as the breath of life remains in them, and when wisely regulated, and excess is restrained, it is often better that they should continue to be so, even in their invalid state. Better let a mountain climber or a fisherman take some risk and climb and fish a little, than to wear out his life in desponding *ennui*. I recall the case of a poor fellow with advanced phthisis whose hollow cough kept the ranch awake at Estes Park, and who would still persist in his favorite amusement of trout-fishing whenever he was able to drag his emaciated form to the streams. When I left the Park I expected that a few weeks would see the end of him. What was my surprise to learn that he was still fishing there the following summer, and I trust that he is still somewhere whipping the brooks and so prolonging, not altogether unhappily, his precarious existence.

Those, on the contrary, accustomed to sedentary habits, as so many women are, and not a few men, it is more difficult to indulge safely in their proclivities; for a change of climate, for whatever disease, requires a more active life generally than the one they have been leading; nature, however, reasserting herself, aids us in this, for, in the natural state, man, like most other animals, is an active creature, and it is only the artificial caging that contravenes nature's law. While, then, the old order is changing, reverting to the normal, we can temporize a little to the benefit of the mental state by allowing something of the old life to continue, changing, if we can, the method and manner of it.

For instance, we can send a man given to historical research, and who spends much of his time in his library, to Santa Fé or to the old mission towns of Southern California, where he can investigate the bygone history of these old places, rich in the fascinating tales of Indian missions and self-denying padres. Naturally, in doing this he will be much out of doors and more or less active. So you gradually change his previous mode of life and indulge his mental inclinations.

Or, again, it is a woman who has too assiduously devoted herself to charitable work. Her work has become almost her life, and to separate her from it entirely is to destroy her aim and object in life. If she goes to Aiken, let her gather a class of colored people about her to teach a little, or visit them in their cabins à la friendly visitor. Or if to New Mexico, let her look up the Indians. So, again, you keep alive hope and interest in life, which, in its turn, keeps alive the body.

The separation of families and of intimate friends for a considerable period of time is a serious obstacle to the kindly influences of a healing climate. In cases where the social and family ties are of the closest, and the dependence of the patient upon those about him is great, it is a question in my mind whether enough is gained, by sending him long distances to some of the standard climates, to compensate for the loss entailed in mental stamina by the shock of the separation. In certain cases which have come under my observation, where, for instance, a wife has been sent from the east to Colorado, and could see her husband but once a year, or a daughter or son sent away from the rest of the family, it has hardly seemed to me that the climatic gain compensated for the loss of that peace and contentment of mind so essential for favorable progress in any chronic disease. Of course, individuals vary much in the manner of adapting themselves to circumstances and the inevitable. Where, however, the longing for the dear ones at home is extreme and continued, a spot nearer home with a climate less intrinsically ideal for the disease, but affording easy communication with the home friends, may accomplish better results; as, for instance, Sharon, in this State, or Lakewood, in New Jersey. Often it can be so arranged that members of the family can accompany the invalid, but sometimes not, as in the case—not infrequently arising—of a wife whose husband is confined at home by business or professional life, and upon whose labors the very ability to enjoy the new climate depends. Most people, it seems to me, hardly realize the shock which the separation from friends and familiar scenes produces, especially upon those of middle age, and upon those who have few resources within themselves. If a certain climate is considered a *sine qua non*, then it would seem wise in such cases to insist upon certain of the home friends accompanying the invalid, or, better, the whole family. The roaming life of the prairie schooner class, where the whole household go along, has other advantages besides its idyllic character; they carry home with them.

An environment of invalidism is almost inevitable in most of the well-known health resorts. Besides its injurious influences in other respects, mentally it is in many ways unfavorable. To be sure, calamity in a way makes us all akin, and in thinking of and helping an unfortunate brother our mind is diverted from our own misfortune to our benefit. On the other hand, however, to be amongst many others suffering

from the same disease as ourselves, in its varying degrees and phases, must often react unfavorably upon our own condition. Our disease is kept constantly before us; and I have noticed that a community of invalids seem morbidly eager to discuss their own symptoms, and learn to watch and note the smallest variations in their condition. When thus the mind is kept constantly upon the disease, the progress is naturally less favorable. Again, death must often occur in a community of invalids, which reminds, most emphatically, the survivors of the uncertainty of the issue in their own case. So the dread and doubt are kept constantly before them, and their mental attitude is anything but one of peace and calmness, which is of paramount importance if one would obtain the best results. I must confess that this seems to me to be a serious objection to such health resorts as are exclusively devoted to invalids and to those of the same disease; resorts, moveover, which are of narrow confines, like Davos, for instance. Is not the objection all the greater to sanitaria, where many invalids are under one roof, particularly if the disease is phthisis? It seems difficult, nevertheless, to obviate this. Naturally the physician desires to send his patient, and he to go, to the climate supposed to be best suited to his disease, and so, as a result, they collect at the few well-known localities. A wider and better personal knowledge of climates and a careful study of the individual patient can do something toward remedying this. The same or as favorable a climate as the one we think best adapted to our patient, and represented by a health resort centre, can often be found which has not yet been invaded by the army of invalids, and which, at the same time, possesses favorable conditions enough in other respects, such as food, lodging, companionship, diversion, and the like, to answer to the demands required by our patient. In the great climatic range of Colorado it would be pretty easy to do this, it seems to me, or in the high pine belt of the South, though here the matter of good food and accommodations might be a difficult one. Again, a sea voyage might accomplish it. Certain it is that the influence of an environment of strong, healthy, and consequently cheerful, individuals about an invalid is more conducive to rapid improvement and hopeful anticipation, than one of invalids with the constant reminder of "Memento mori."

Lastly, the age of the patient as a psychological factor is important in considering the effect of the change to be made. "Hope," it is true, "springs eternal in the human breast," but it springs more exuberantly in the young human breast, and we can count more upon this universal element in human nature in the young than in the middle-aged and older. The adaptability of the young to changed and new conditions is great, and with them we can venture on more radical changes than with the older, who are bound by long association to friends and places. Not infrequently it may be a question whether, with our older patients, it is wise to take the risks of an abrupt and radical change. At all events, if it is decided upon, more care should be taken to surround the invalid with some semblance of his former environment, so that he may more readily take root in the soil to which he is transplanted. After all, to keep him within a shorter radius of home may seem the wiser thing, the greater contentment and hopefulness retained by so doing compensating for the loss incurred by being in the less favorable climate.

In conclusion, I hope that I have emphasized some points often too lightly passed over in the very serious consideration involved in settling the question of change of climate for our patients. From my own experience and observation, it has seemed to me that these psychological factors, as I have called them, have not been given as careful consideration as their importance demands. Ours is a material and scientific age, and medicine feels the influence of the time and age; but there is a spiritual as well as a physical side to the human entity, and he is the wise physician who duly weighs in his considerations and decisions the influences of the spiritual side as well as that of the physical. "The doctor," says Wilks, "soon finds that in treating his patient the practice of medicine is not only one of physic, but of psychology, and that the effects of his drugs depends as much upon the constitution of the patient's mind as his body."

THREE RARE CASES ILLUSTRATED. MULTIPLE PAPILLOMATA OF THE VELUM; IMMENSE FIBROID TUMOR OF THE TONSIL; AND FIBROID TUMOR OF THE NASAL SEPTUM.

BY GEORGE M. LEFFERTS, A.M., M.D.,

PROFESSOR OF LARYNGOLOGY, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

THE cases illustrated herewith are of a rarity that justifies me in presenting them.[1]

The physical appearances of the tumors are well shown in the drawings, and require, therefore, no detailed description.

The differential diagnosis, in cases as well marked and distinctive as these, presents no difficulty; macroscopical signs alone will suffice for the recognition of their true nature.

Although papillomata are the commonest variety of true neoplasm of the fauces, a growth the size of

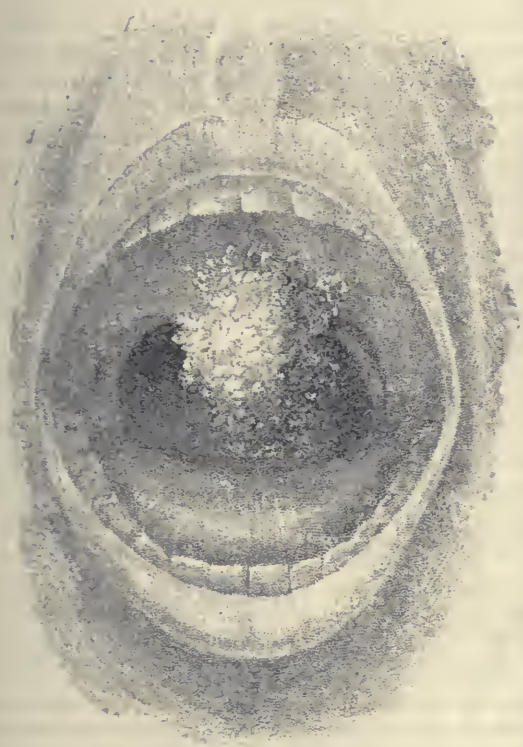
---

[1] Eleventh Annual Congress of the American Laryngological Association.

that shown in the present instance must be very unusual. It occurred in

Case I.—A girl, æt. sixteen, who only accidentally noticed its presence in her throat when it had attained fully one-third of the dimensions here shown. Thereafter it grew rapidly and in eight months time resembled the drawing. Little or no inconvenience was caused, dysphagia never being present and but slight interference with the timbre of the voice.

Fig. 1.



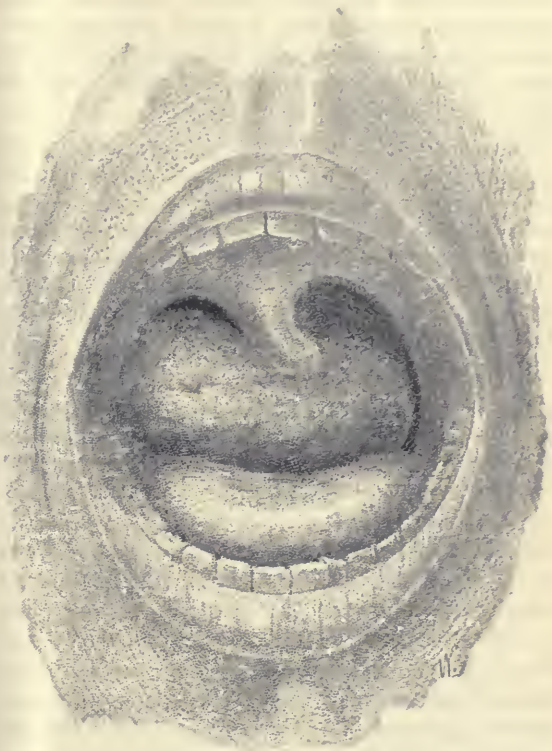
Papillomata of the velum.

After anæsthesia of the parts by cocaine the multiple tumors that made up the mass were removed by scissors curved on the flat. The uvula was not involved and was left intact. A superficial stellar cicatrix now shows the former site of the sessile portions of the growth. There has been no sign of recurrence.

Case II.—A man, æt. fifty-five, who for many years had been aware of the existence of a slowly growing tumor in his throat; but increase in size being gradual, and no pain, interference with deglutition, nor embarrassment in respiration having, until lately, been experienced, no operative procedures had been allowed.

Now, at the date of examination, dyspnœa at night when in a recumbent position, and difficulty in the deglutition of both fluids and solids, the growth descending during the act and blocking the path to the œsophageal mouth, demand surgical relief. From the region of the right tonsil—the latter being involved in the growth—sprang the large, dense tumor, covered by a thin non-vascular mucous

Fig. 2.



Fibroid tumor of the tonsil.

Fig. 3.

Fibroid tumor of the nasal septum.

membrane, that is shown in the drawing. It possessed a more or less distinctly defined narrowing at its point of attachment, which rendered it an easy matter to encircle it at this point with the wire of the écraseur. This was done by Dr. C. E. Beebe and the tumor thoroughly and neatly removed. No hemorrhage.

CASE III.—Man, æt. thirty-six. I am acquainted with no instance in practice or literature of a *fibroid* tumor springing from the *nasal septum*, save the one here shown. The little tumor was hard and dense, its covering a thin, vascular, mucous membrane, and it was distinctly pedunculated by a delicate pedicle, the latter attached to the nasal septum, just above the muco-cutaneous junction, in the right nostril. The sole symptom caused by its presence was occlusion of the right nasal passage, the discomfort of which had caused the patient to seek advice. He was unable to state how long the growth had existed.

The pedicle was cut through with scissors and the tumor removed.

THE PATHOLOGY OF HEMOPTYSIS FROM CHRONIC PULMONARY DISEASE.[1]

BY G. M. GARLAND, M.D.,
INSTRUCTOR IN CLINICAL MEDICINE IN HARVARD UNIVERSITY

FOR the convenience of discussion, we will assume that we are considering only cases of true pulmonary hemorrhage, wherein all extraneous sources of blood supply, such as aortic aneurism, cardiac rupture, etc. have been ruled out of the symptoms of the case. We can then roughly divide pulmonary hemorrhages into two groups: (*a*) cases which present physical signs of pulmonary disease, and (*b*) cases in which no physical signs of changes of lung structure can be found.

Our knowledge of the pathological causes of hemorrhage in the first group has been thoroughly digested and organized by Virchow, Thompson and others. We know that hemorrhages proper in this group come from deficiencies in the pulmonary system of vessels, while bronchial hemorrhage, or leakage from the arterial supply of the bronchial tubes, is slight in quantity and merely streaks the accompanying secretions of those tubes. No inference can be drawn from the color of the blood as to its source, because the oxygenation of the pulmonary blood is so rapid that it is expectorated red. Blood which has lain stagnant in the tubes over night may, of course, look dark. Traumatic injuries of the vessels, aneurism, and diapedesis are familiar causes of hemorrhage in tuberculosis. According to Virchow, however, the greater number of hemorrhages in phthisis come from ulceration of the vessels.

In the second group, we find no clinical evidence of changes in the pulmonary parenchyma. We may, indeed, locate the presence of blood in the bronchial tubes, but this does not necessarily determine the seat of the leakage, because the blood is rapidly drawn off into by-ways and side-issues, quite remote from its point of departure. The presence of hemophilia, scurvy, and habits of excessive drinking would lead one to consider alterations in the composition of the blood itself as a possible cause of hemorrhage. Some evident point of departure for an embolus, the possibility of thrombosis, the previous inhalation of irritating fluids, are matters for deliberation in diagnosis.

Pulmonary congestion is not of itself alone a prolific cause of hemorrhage. Thus veritable hemorrhage is a rare complication of pneumonia, and yet that disease produces high grades of congestion. In whooping-cough and congestive bronchitis the amount of blood is rarely copious, and is the result of violent coughing. One writer has observed that hemorrhages are rare in acute maladies of the respiratory apparatus, and any pulmonary congestion which is not symptomatic of a cardiac affection is rarely accompanied by the expectoration of veritable blood.

This brings us to the consideration of the heart as a factor of pulmonary hemorrhage. Fernet says: "After tuberculosis, heart disease exerts the greatest influence in producing hemoptysis," and mitral troubles stand pre-eminent in the causative list. Here, also, the element of exertion comes in, upon which Thompson lays so great stress. He says:

> "The influence of exertion in the etiology of blood-spitting has not received so much attention as it deserves from the importance and frequency of the event, for cases occur in which hemoptysis has followed some unusual exertion, in which no positive proof of pulmonary disease can be shown to exist. . . . Prolonged exertion in walking and running leads to excessive hyperæmia of the lungs, consequent upon the rapid emptying of the veins into the right side of the heart, and either the lungs give way under a condition of general congestion with extravasation of blood, or local apoplexies of a similar kind occur; or, on the other hand, the heart may become overstrained, and give way in a condition of general dilatation."

The following case, under my own observation, will illustrate the pertinency of the above quotation:

Mr. A., thirty-seven years of age, had smoked to excess for many years, and also had a history of spitting blood about twelve years ago and also once or twice since then. On August 26, 1887, he attended a convivial dinner, and on the next afternoon he played lawn tennis very energetically. That evening he raised a considerable amount of blood, and again the next day. On August 29th, I examined him, and found a few coarse and medium râles in the left sub-scapular space, and a slight diminution in the volume of resonance over the same region. There were systolic murmurs in the aortic and mitral areas, and the heart apex was considerably outside the mammary line. The bleeding stopped

[1] Read before the American Climatological Association, June 25, 1889.

in a couple of days, and the patient was advised to avoid all smoking and all active exertion.

My notes for January 29, 1888, report, "No râles or dulness in the left sub-scapular space. Heart more regular, and murmurs faint."

In February, 1888, after walking against a strong, cold head-wind, he had another hemorrhage, with return of physical signs in the left sub-scapular space. The signs faded out more slowly this time.

On March 13, 1889, I found no dulness and no râles. The patient is strong and well, and is heavier in flesh than ever before. About six weeks ago, however, he raised a few mouthfuls of blood on the day following a plunge into the cold-water tank of the Athletic Club. The temperature of the water was about 68° F.

Still another group of cases calls for our attention, wherein none of the above conditions can be established. The lung simply bleeds, and there is nothing else to show for it. Some of these cases eventuate in phthisis. Some do not, and the crying appeal is to know if such cases are tuberculous at the outset. I can find no decisive answer to this question, though both sides have been maintained with hot fervor. The fact that all cases do not develop into phthisis is no argument, because all cases of tuberculosis do not advance to phthisis. The only solution of this problem lies in a critical microscopical search for bacilli in every fresh case of hemoptysis.

There is one suggestion regarding pulmonary hemorrhage which has been advanced by Virchow and others, but which has received less attention from clinicians than it deserves; I refer to the influence of the nerve centres. Virchow says: "If we cannot deny, therefore, the greater frequency of hemorrhage by certain weather conditions, especially by weather changes, yet it appears that here also a contributing cause (Wallungszustände) must be sought, which possibly lies in the nervous system."

We have already seen that pulmonary congestion, *per se*, is not sufficient for hemorrhage, inasmuch as pneumonia and other acute congestive processes of the lungs are distinguished by the rarity of hemorrhage. Moreover, Cohnheim has shown by his experiments upon embolism, that mere congestion is ineffective for bleeding in other organs. He induced an artificial embolism in the frog's tongue, by introducing small particles of wax into its circulation. The first effect was a severe congestion in the neighborhood of a vessel occluded by a bit of wax, but no hemorrhage occurred. Not until three or four days later was a hemorrhagic infarct formed; the blood cells then did not extravasate indifferently, but all of them passed through selected points and grouped about the same. These points were not otherwise distinguishable in their appearance. Hence, Cohnheim concluded that diapedesis is not due to the presence of a congestion, but to changes in the constitution and resistance of the vascular walls.

Admitting these facts, we ask if similar changes in the condition and resistance of the vascular walls can be wrought by any perversion of nerve influence alone, and we receive an immediate answer in the affirmative. I need only refer to a few illustrations. We are all familiar with the ecchymosis which forms on the under lid of suicides when the bullet has pierced a certain part of the brain. Schiff has shown that lesions of the cerebral peduncles can determine ecchymosis in the mucous membrane of the stomach; Brown-Séquard has produced hemorrhages in the lungs by lesions of the pons; Strauss speaks of the ecchymoses tabetiques upon the extremities following severe pain; Faisans and Kellar describe subcutaneous hemorrhages resulting from great moral commotion in neuropathic persons; vicarious menstrual hemorrhages are a common experience, and it is interesting in this connection to note that out of two hundred cases collected by Puech, hemoptysis figured twenty-four times—*i. e.*, in twelve and one-half per cent. Great weight is laid by Virchow upon a certain condition of the arteries themselves, which he called Wallung, or orgasm, and he evidently believes this Wallung to be under the direct control of the nerves. Affluxus of blood, he says, to the locality of an irritation, does not comprehend to-day the history of the blood Wallung. Of course, Wallung occurs upon irritation, but it is not always limited to the locality of the irritation. It may appear sympathetically at points greatly remote. Illustrations of this condition are observed in the pulsatio epigastrica of hypochondriacs; in the heat-flushes of women during the climacteric; in the pulsations of the head in cephalalgia; in the throbbing of a temporal artery with the toothache. Moreover, this sensation of Wallung is also felt in the chest and sometimes precedes a hemorrhage which removes the disagreeable sensation, according to the evidence of patients.

In conclusion, therefore, I would say that I believe that a more careful discrimination of our cases of pulmonary hemorrhage, would reveal some of purely neurotic origin.

HOSPITAL NOTES.

JEFFERSON MEDICAL COLLEGE HOSPITAL.

SERVICE OF J. M. DA COSTA, M.D.

(Reported by E. P. HERSHEY, M.D., Clinical Assistant.)

PSEUDO-HYPERTROPHIC PARALYSIS.

P. H., ætat. nine. For over a year has been under observation. He is now barely able to walk. When he first began to walk, it was with great difficulty. There is no history of spasm or acute attack. His walk is a

curious waddling one, the feet turned in, and he steps on his toes. The manner in which he gets up and stands on the tips of the toes makes us suspect at once that there is something other than mere paralysis. Removing his clothing, we are at once struck with the disproportion in the size of the muscles of the legs. The enormous increase of the muscles of the calves, not simply posteriorly but laterally. The bones are not enlarged, and there is perfect symmetry in the enlargement on both sides. The calves are very hard and firm; there is no sensitiveness in the muscles. Each calf measures ten and a half inches in circumference. He has been walking on his toes only during the past six months.

The muscles on the back of the thigh are dwindling; there is some hardness of the hamstring muscles, mostly on the right side. Both the biceps and triceps are small; there is certainly no enlargement. Has great difficulty in rising from the floor; first he gets on his hands and feet, then places one hand on his knee, then the other; the hands then, one after the other, are placed on the thigh, and he then rises with great exertion.

They may be other muscles implicated. Examining the upper extremities, we find the pipe-stem arms, the dwindled biceps, the same hardening of the triceps as was found on the legs. The inferior portion of the pectoral muscles is atrophied, the left side is extremely small. In the lower part there is apparently no muscular structure; this is not so marked on the right side. The infra-spinatus is not hypertrophied on either side. There is some atrophy of the latissimus dorsi muscles. The right shoulder is slightly higher than the left; there is no marked spinal curvature—evidently too early in the disease for this.

The boy is very bright. There is no disease of the heart. Its action is distinctly irregular: a series of slow beats, followed by rapid ones, 90 in the minute. The first sound is short, the second sound is exaggerated. The eye-grounds have been examined with negative results. The tongue is large and slightly coated; appetite good; bowels are regular.

Microscopical examination of the muscular tissue, taken from the gastrocnemius muscle of the right side by means of the muscle trocar, shows the muscular fibres to be in a condition of granular degeneration; an increase of connective tissue, oil globules taking the place of muscle cells; much of the muscular striæ lost, and here and there a narrowing of the fibres.

Here we have a disease that has slowly progressed from infancy, but was only made manifest to those about him when he first attempted to walk. The boy is of the classical age for what we have here, the rare malady, pseudo-hypertrophic paralysis. This affection usually occurs between the ages of three and ten. If it does not develop until the child reaches its tenth year, it is apt not to happen. This is not absolute. It may come on at the age of puberty, but in the vast majority by the tenth year the disease has so fully developed as to be readily recognized. This case is not coexistent with any cerebral or spinal lesion. There is no history of tardiness in the mental development, no history of convulsions. We find the spinal nervous system not quite normal. A little perverted sensibility in the legs, no anæsthesia. A striking point is the absence of the patellar tendon reflexes; there is absolutely no response. In our electrical examination we find marked diminution in response both to the faradic and galvanic currents, in the inferior spinatus, the biceps and triceps, the glutei, and the extensors of the feet. In the vastus internus there is scarcely a perceptible response; the gastrocnemii respond.

The seat of the lesion is not in the central nervous system. It is inherent in the muscular system. There is a possibility that it may be in the periphery of the nerves. The reasons for the assertions are: first, the age at which the disease manifests itself. All degenerative lesions of the nervous system, except essential paralysis of infancy, happen, not in children, but in adults. The very age, therefore, is an argument against a central lesion. Again, another strong argument against it is, that the autopsies made, summing up all our knowledge on the subject, are negative in regard to changes in the anterior cornua. The affection is essentially muscular; but we need further observations on the possibility of lesions of the peripheral nerves. The absence of reflexes is very significant.

The disease is strongly hereditary. In this case we have been unable to elicit any family history; this is the only child in a family of six that has the disease. It is apt to be transmitted through the mother. While it may go through the family, the mother herself escapes, the girls escape, and the boys take it.

Treatment.—There have been no favorable results in trying to modify the disease by means of alteratives. Indeed, no internal treatment is of much avail, If anything, Fowler's solution, gtt. ij t. d., and the dose gradually increased may be tried. Careful exercise; massage; mild faradic currents to get muscular action without altering the tone may also be used.

MEDICAL PROGRESS.

Hot-air Inhalations in the Treatment of Phthisis.—Since the valuable contributions of Cornet, the prophylaxis of tuberculosis has assumed a reasonable and applicable form, yet the profession feels almost as much in the dark as ever regarding the therapeusis of this dread disease. Although there is perhaps no other disease for which there are so many reported cures, yet we are forced to confront the fact that there is no disease the prognosis of which is so doubtful and discouraging. Still, medical science is actively seeking for some efficient therapeutic method. Of investigators there is indeed no lack.

Notably among the most recent methods of treatment is that of hot-air inhalations first suggested by Weigert, who patented an apparatus for this purpose and published a popular treatise entitled, "Consumption and its Cure." His method has already been extensively investigated.

RENZI[1] carefully noted the physiological effects of the inhalation of air at a temperature of 284° to 329° F., and found that the respirations were accelerated and the pulse quickened. He then applied the treatment to several patients suffering from phthisis, and arrives at the following conclusions:

1. The inspired air must, in order to exert any beneficial action, be of a very high temperature. Inhalations

[1] Morgagni, No. 17, 1889, and Centr. f. die gesammt. Ther., June, 1889.

of air at a temperature of 110° to 120° F. have no influence whatever.

2. Inhalations of air at temperatures varying from 176° to 320° F. were endured without inconvenience to the patient.

3. The minimum temperature for the inhalations should be about 320° F. Each *séance* should last from fifteen minutes to an hour.

4. In one case the inhalations were followed by hæmoptysis, but, as the patient frequently had had hemorrhages prior to the inhalations, the symptoms could not be positively ascribed to the treatment.

5. In every case in which the treatment was employed, there was a marked improvement in the general condition of the patient and an increase in strength.

6. In a few cases there was an increase in the bodily weight and a decrease of the number of bacilli in the sputum; both the action of the heart and the respirations were increased; there was also a rise in temperature.

According to the above conclusions, one would be led to consider the treatment merely palliative.

The results of Dr. Kohlschütter[1] are, however, more definite, and confirm the results obtained by Weigert. Kohlschütter advises the inhalation of even hotter air than that used by Renzi; the thermometer on his apparatus registering as high as 482° to 572° F. during the application of the treatment. Of course, the air actually inspired was much lower than this; still the temperature must have been very high, as the expired air was 110° F.

Kohlschütter's experiments extend over a period of seven weeks, during which time numerous patients were subjected to the treatment. The principal results obtained by him were, first, marked increase in the expansion of the chest; in one case the increase being three inches. Second, where a pleuritic exudation had existed, this disappeared, likewise râles and other symptoms of abnormal breathing. Third, the depth of the respirations was also materially increased. Fourth, microscopical examination showed a decided decrease in the number of bacilli in the sputum. Most notable, also, was a change in the bacilli themselves; whereas, prior to the treatment the bacilli were found equally distributed all through sputum in the typical "row of beads," as well as the flat form, they were, after the treatment, found only in clusters of three and four, and the flat form were no longer to be found.

A slight rise of temperature, similar to that noted by Renzi, was also observed by Kohlschütter; the latter investigator also observed that the respiration became slower, as well as deeper. Shortness of breath entirely disappeared in all cases. At first expectoration was considerably increased, but after a continuance of the treatment it became greatly lessened. The appetite was invariably improved, and the patient's weight increased. Kohlschütter is still actively investigating the subject.

The most recent results obtained from this treatment are those of Dr. George G. Sears, of Boston,[2] who reports four cases which he treated with hot-air inhalations, the temperature employed being about 392° to 428°. His experiences are far from confirming those of Weigert, Renzi, or Kohlschütter. Briefly stated, they are as follows: In one case temporary improvement was quite marked, but at the time the treatment was discontinued there had been a further advance of the disease, and for the first time in her illness hæmoptysis occurred. In one case the inhalations were omitted after one week, owing to salivation and soreness of mouth, with a loss to the patient of three pounds in weight. In another case there was also fairly steady improvement in the general condition of the patient, but without corresponding improvement in the physical signs. She had, however, already begun to improve before the inhalations were resorted to. Five days after they were discontinued, death resulted from hemorrhage. In the fourth case the condition of the patient remained unchanged, except that during the treatment blood was found in the sputum for the first time. Although Sears in every case carefully subjected the sputa to frequent microscopical examinations, no decrease in the number of the bacilli was noted.

In conclusion, we may draw the following inferences:

1. Inhalations of air at a very high temperature (from 350° to 360° F.) are capable of producing, in many instances, a marked improvement in the general condition of phthisical subjects. The permanency of these improvements are, however, extremely doubtful.

2. The influence of hot-air inhalations upon the growth of the tubercle bacilli is uncertain. It is probable that the bronchial secretions are sterilized by the inhalations, but their influence upon the bacilli deeply imbedded in the pulmonary tissue is most doubtful, as the inspired air by the time it has penetrated into the deep lung tissues becomes so cooled that any germicidal property is highly improbable.

3. Symptoms of hæmoptysis having been observed to follow the use of the inhalation, indicate that great caution should be used in the application of the treatment.

4. The treatment, at best, should be considered palliative or prophylactic rather than curative.

Treatment of Uterine Cough.—The *Revue Gén. de Clin. et de Thér.* of June 27th states that valerianate of quinine will be found most valuable in the treatment of uterine cough. Its beneficial action is ascribed to its antispasmodic properties, as the affection itself is of a reflex nature. The drug may be prescribed either in solution or pill form. If the former is used, the addition of an infusion of black coffee will be found valuable.

I.

℞.—Valerianate of quinine . . grs. xv.
Infusion of black coffee . . f℥jv.
Simple syrup . . . . f℥jss.—M.

Sig.—One, two, or three large spoonfuls after meals.

II.

℞.—Valerianate of quinine } . . s. a.
Extract of quinquina }

Divide into ten pills.
Sig.—One pill after each meal.

Indications for Iridectomy and Sclerotomy in Glaucoma.—Dr. Loshechnikoff, writing in an ophthalmological review, published at Kieff, gives a *résumé* of 284 scle-

[1] Inter. klin. Rundschau, No. 10, 1889.
[2] Boston Medical and Surgical Journal, July 11, 1889.

rotomies performed by him while attached to the ophthalmic clinic in Moscow. The operation employed was Wecker and Mauthner's double sclerotomy. There were eight cases of acute glaucoma, sixty-eight of chronic glaucoma from inflammation, ninety-three of absolute glaucoma, seventy-one of incipient, and eleven of simple glaucoma. To each series is added a table of effects on tension and sight. The effect is called "excellent" when T. (tension) becomes normal, or less than normal, and central sight increases; "good" when T. decreases and V. (vision) remains the same; "medium" in cases of *status quo ante*, or when V. is somewhat worse, but T. decreased, or when there is a little improvement of V. with permanent T.; "bad" when V. is worse and T. permanent. In Table III., which deals with absolute and degenerative glaucoma, the author often says: "V. improves," "V. remains unaltered," though we are accustomed to use the expression "absolute" only in complete blindness from glaucoma. The author, however, claims for this series the best results—no less than 82 per cent.

The following are some of his conclusions: Iridectomy is indicated in chronic and subacute glaucoma. In absolute glaucoma, with symptoms of degeneration, sclerotomy is indicated. In acute glaucoma sclerotomy is a preliminary operation, to be followed generally by iridectomy. Sclerotomy is, for the sake of appearance, preferable to iridectomy, and holds out better prospects for the improvement of sight. It is consequently indicated in incipient glaucoma. In simple glaucoma sclerotomy is preferable. In all cases of imminent prolapse of the vitreous, and especially in congenital hydrophthalmus, sclerotomy is indicated. In secondary glaucoma iridectomy is always preferable. It is absolutely necessary to use eserine before sclerotomy.—*The Lancet*, June 22, 1889.

Laparotomy upon a Newborn Infant.—A successful laparotomy for umbilical hernia on a child but one hour old, is reported by DR. PHŒNOMENON, of Kasan, in the *Revue Gén. de Clin. et de Thér.* of July 11th. The child was born with a large umbilical hernia, and, within an hour after the ligation of the cord, was chloroformed and operated upon. Antiseptic precautions were carefully observed, the abdominal cavity sterilized, and the sac, peritoneum, and wound sutured successively. Recovery was rapid, complete, and devoid of any complications. Such serious operations in so young a subject are still among the rarities of surgery.

Salve for Scrofulous Keratitis.—DR. SAINT-GERMAIN gives the following salve for scrofulous keratitis in *L'Union Médicale* of July 6th:

℞.—Yellow precipitate of mercury . grs. xv.
Vaseline . . . . . ʒiij.—M.

With the aid of a pair of pincettes, or a paper spill, a small quantity (about the size of a pea) of this salve should be placed under the lid, and then the latter gently rubbed so that the ointment becomes spread over the entire surface of the eye. The result will be most satisfactory.

Local Application of Chloroform in Epididymitis.—DR. THEODOR CLEMENS, of Frankfort, in an interesting paper communicated to the *Allgemeine medicinische Central Zeitung*, describes the great benefit he has obtained in cases of epididymitis, both specific and non-specific, by means of chloroform locally applied. He regards as most unsatisfactory the treatment of the affection by other methods as compared with his own, which he has employed now for a great many years. It consists in laying some cotton-wool saturated with chloroform and spirit at the bottom of a large glass vessel, into which the genitals are then put and packed round with dry cotton-wool, the buttocks and thighs forming a cover, this application being continued for from fifteen to twenty-five minutes, and repeated two or three times a day.

Pathologically, he considers venous congestion of the epididymis and the cord through retention of semen a predisposing cause of the disease. He also considers epididymitis as very likely to occur when gonorrhœa has been contracted in excessive venery.

He mentions a case of treatment by chloroform thirty-six years ago, not of epididymitis, but of periodical "heat" occurring in the human subject. The man used to suffer periodically from a form of orchitis, during which the testes felt hot and swollen, and the plexus pampiniformis was full and turgescent like a varicocele. He was ordered the local application of chloroform three times a day, from fifteen to twenty-five minutes each time, but the first time he bore the chloroform for nearly thirty-five minutes, after which the pain of the severe attack completely ceased and the swelling considerably decreased. This treatment lasted three days, during which time he was able to walk about, the cotton-wool which had been used for the chloroform being put into the suspensory bandage and the testes covered with it. After that both the swelling and sensibility disappeared. Another case is mentioned, in which epididymitis had been caused by the continuous pressure of a rudder handle on the hypogastrium, in which similar treatment proved entirely successful.

Again, a class of case that is usually very difficult to treat—viz., that of gonorrhœal orchitis—seems to have proved fairly tractable when managed with the help of chloroform. Here one of the first signs of improvement was frequently the reëstablishment of an old discharge, which was soon cured simultaneously with the epididymitis.—*Lancet*, July 13, 1889.

An Expectorant Potion.—The *Union Médicale* of July 11th, recommends the following:

℞.—Powdered ipecac . . . . grs. v.
Oxymel of squill . . . . fʒvss.
Syrup of ipecac . . . . fʒj.
Infusion of senega . . . fʒiijss.—M.

Make potion.

Sig.—Give in teaspoonful doses. It will facilitate the expectoration of mucus and relieve bronchial inflammation.

New Therapeutic Properties of Antifebrin.—We read in the *Centralbl f. d. gesam. Therapie* for July that DR. ERNST JENDRÁSSIK has discovered additional and most important therapeutic properties in antifebrin.

In those typical attacks of excitement, and even violence, which occur in tabes and dementia paralytica, eight-grain doses of antifebrin acted as a rapid calmative,

the excited condition of the patients quickly giving place to a state of repose under its influence. The paralytic attacks were also greatly shortened by its use.

Jendrássik also used similar doses of the drug with great success, in combating the laryngeal spasms of tabetics. These spasms, which usually occur near bedtime, cause the patient profound distress and frequently necessitate him to leave his bed and pass an almost sleepless night. In every case, however, where, as soon as the symptoms of the oncoming attack manifested themselves, antifebrin was given, the spasms were almost invariably aborted.

A Diagnostic Sign of Early Pregnancy.—At a recent meeting of the Medical Soeiety of Giessen, Dr. Löhlein read a paper on the subject of the early diagnosis of pregnancy, and, after discussing the various diagnostic signs now known, mentioned a new one, by which it is possible to diagnosticate pregnancy during the second or third month. At this time there is a characteristic softness, compressibility, and elasticity of that part of the corpus uteri nearest the cervix. This may be felt by bimanual examination, one finger being introduced into the rectum and one hand pressing the abdomen.—*Deutsche med. Wochenschrift*, June 20, 1889.

The Administration of Chloroform by Gas-light.—As is well known, says the *Lancet* of July 27, 1889, it has been the practice to avoid the use of ether for anæsthetic work if artificial light is needed, whenever there is fear lest the ether vapor mixed with air be heated sufficiently to explode. The heavier vapor of chloroform, in addition to not being liable to form an explosive mixture with common air, is far less inflammable, and so has been hitherto regarded as a safe anæsthetic in such cases, at least as far as dangers from fire are concerned. Recent researches undertaken by Dr. Iterson, however, seem to show that chloroform vapor, when allowed to mix with the products of combustion of ordinary coal gas, undergoes decomposition and liberates gases of a most irritating nature. Dr. Iterson believes death has been brought about in one case at least by inhaling the noxious vapors, and recounts other instances in which alarming symptoms have supervened. One patient, although apparently but little affected while inhaling the chloroform, became painfully dyspnœic afterward, gasping and evincing the usual symptoms of asphyxia due to irritant vapors. These alarming effects passed off when the windows were thrown open and the fumes of coal-gas combustion and chloroform were permitted to escape.

It is well known that samples of chloroform which have been kept exposed to diffused light will after a while become contaminated with chlorine and acid substances, which possess most irritating properties; but until Dr. Iterson's warning arrived, we were not aware that chloroform vapor would, when diffused in the air of a room or operating theatre, be decomposed in passing over a jet of ignited coal gas. We know that, heated to redness, chloroform splits up into hydrochloric acid, chlorine, and other products, including the trichloride of carbon; and both Soubeiran and Liebig have pointed out that, although chloroform vapor cannot be ignited in the air, it will, if passed over a spirit-lamp flame, burn, and liberate irritating vapors. The question as to the gases most probably formed, if the coal gas is capable of uniting with the products of chloroform decomposition, is too wide a one for us to enter upon; nor do we think that we need go farther than to say that, if Dr. Iterson's facts are to be taken without reservation, the irritant bodies which exercised so deleterious an influence were, in all likelihood, the products of the ordinary decomposition of chloroform—namely, free chlorine, hydrochloric acid, and possibly other chlorides and ammoniacal compounds.

The Treatment of Tooth Rash.—Dr. E. Besnier, says the *Gazette Méd. de Nantes* of July 9th, considers that the rash appearing on the hands, wrists, and back of infants during teething to be caused reflexly by facial rash, the latter being induced by the copious flow of saliva from the mouth due to the irritation of the gums.

In treating this rash, therefore, he recognizes the following indications: first, to ease the irritation of the gums; second, to relieve insomnia; third, to relieve the rash itself.

1. To ease the irritation of the gums, he advises that they should be frequently and gently rubbed with the finger, which has been dipped into the following mixture:

℞.—Hydrochlorate of cocaine . gr. ¼.
Bromide of potassium . . grs. viij.
Distilled water } . . āā f ʒ iij .—M.
Glycerine }

2. To relieve the insomnia, a tablespoonful of the following formula may be given every hour:

℞.—Bromide of sodium . . grs. v to viij.
Syrup of orange flowers . f ʒ ij.—M.

3. For the treatment of the rash, the following salve should be constantly applied:

℞.—Oxide of zinc . . . ʒ iij.
Vaseline . . . . ʒ j.—M.

Strangulated Ovarian Hernia in an Infant.—The following interesting case is reported by Mr. Bilton Pollard, F.R.C.S., in the *Lancet* of July 27, 1889:

E. R., a female child aged three months, was admitted into the Northeastern Hospital for Children, on March 30, 1889.

When the child was two months old, its mother noticed a lump in its groin; the lump used to disappear for a time and then return; its size was variable. An inguinal truss was ordered at the hospital and applied; the hernia was then supposed to have been reduced. On the 27th the truss was removed, and an irreducible swelling was noticed in the right groin. On the 29th the patient was seen at the hospital by the house surgeon, who found the hernia irreducible. When admitted, there was a swelling of a rather larger size than a pigeon's egg situated over the right external abdominal ring, and distending the upper part of the right labium majus; the skin over it was red and hot; the swelling felt elastic, and indistinct fluctuation could be made out; it was irreducible, gave a dull note on percussion, and altogether simulated an abscess. Soon after admission the child was placed under the influence of chloroform, and an incision one inch and a half long was made through the superficial tissues, which were all œdematous and matted together. The sac contained an ovary and the fimbriated

extremity of the Fallopian tube; they were both greatly swollen, black or gray in color, and in places coated with lymph. The sac and its contents were mopped over with a 1 in 500 solution of perchloride of mercury, the pedicle was drawn down, transfixed, and tied in two pieces with silk ligatures, and the pedicle was returned within the abdomen. The neck of the sac was tied with a silk ligature, and the body of the sac was excised. The wound was made as dry as possible, and the skin brought together with silk sutures. No provision was made for drainage. A dressing of boracic acid powder and salalembroth gauze and wool was applied. The temperature reached 101.2° F. on the day after the operation; it had fallen to 98.6° by the following day; on the fifth day after the operation the temperature rose to 101.8° without any obvious cause; with these exceptions the temperature kept about normal. The dressing was changed daily. The wound healed by first intention. The stitches were removed on the seventh day, and the child was discharged on the eighteenth day after the operation.

Lanolin in the Treatment of Urethritis.—On account of lanolin having the property of adhering to the mucous membrane, DR. STERN, in the *Wiener klin. Wochenschr.* of July 4th, concluded to use it mixed with oil as a base for urethral injections in gonorrhœa and urethritis. His experiments were crowned with great success. The injections should be retained in the urethra for five or ten minutes. Antiseptic or astringent remedies should be added. Stern uses either of the following formulæ:

I.

℞.—Sulphate of zinc . . . grs. viij.
Water . . . . . f. ʒj.
Lanolin anhydrate . . . ʒv.
Oil of almonds . . . . f. ʒijss.—M.

II.

℞.—Salicylic acid . . . . grs. jv.
Oil of almonds . . . . f. ʒijss.
Lanolin anhydrate . . . ʒvjss.—M.

Stern found it necessary to continue these injections for only ten days at the longest; after which he advises the use of injections of a one and one-half per cent. solution of resorcin.

Antipyrin in Enuresis.—The *Prager med. Wochenschr.* of July 3d says that DRS. PERRET and DEVIC have used antipyrin with great success in the treatment of enuresis. Two doses of ten or fifteen grains, given one at six and one at eight o'clock in the evening, had the desired effect. The continuance of the treatment was only necessary for a few days.

Peru Balsam as a Germicide.—The recent and remarkable results obtained by LANDERER with balsam of Peru in the treatment of tuberculosis, have led DRS. BRANTIGAM and NOWAK to make a careful test of the germicidal properties of the drug. Their results are as follows:

(1) Pure balsam of Peru will kill microörganisms inside of twenty-four hours.

(2) Emulsions of the drug, up to a strength of twenty per cent., exerted no specific effect either upon the development or growth of bacteria upon which they were tested (cholera, anthrax, green pus, and subtilis).

(3) The beneficial actions of the drug are probably due to its influence upon ptomaines. — *Wiener med. Presse*, July 7, 1889.

Guafine, a New Antipyretic.—DR. L. BERTRAND has recently reported in the *Bolletino Farmaceutico* for July, 1889, the results of his experiments with guafine:

Guafine is a resin, which Bertrand succeeded in extracting from the leaves of the *psidium pyriferum*, a tree belonging to the myrtaceæ, and indigenous to the East Indies and South America. The leaves contain a considerable quantity of tannin and oxalate of lime and only two per cent. of the resin guafine. The results of numerous experiments proved that guafine was of considerable value in intermittent fevers. An infusion of the leaves or bark of the psidium is said to be a digestive.

Medical Treatment of the Intestines.—In concluding an article on the subject of intestinal obstruction (London *Medical Press* of July 24th), PROF. H. NOTHNAGEL says:

"I may briefly state in one sentence all the treatment I can recommend as an hospital consultant: Absolute abstinence from food; induce the peristaltic action from below; still it from above; and, above all, avoid purgative medicines. Further I know of nothing to add for the guidance of others.

"As regards other methods of treatment, very little can be said, but there are one or two forms of recent origin which I cannot pass without a remark. Washing out the stomach was introduced by Kussmaul as a remedy, but past experience of this form of treatment has nothing particular to commend itself, and has been of very little use. One advantage in using it is that it is a harmless application, and there is not any danger attending its use. The clyster I can always recommend as a most effectual remedy in all forms of fecal accumulations, but it is not suitable for fecal vomiting where there are inflammatory conditions. The object of a large clyster is to break up large fecal masses, but this is to be avoided where there is a tender bowel. Electricity is another remedy which has come into recent favor, and is not without merit. When using this agent it is recommended that both poles be placed over the tender or painful part of the bowel, or one pole introduced into the bowel. The successful cases from this treatment are so few that no opinion can be vouchsafed. There are other drugs, like belladonna, nicotine, and others that might be named, but there is one regularly prescribed drug that might be noticed. There was a time when every case of stoppage of the bowel must be drugged with mercury, but the greater number of the observers of this treatment have spoken very adversely of it. No doubt an individual case has arisen where success may be attributed to the drug, but these are very few, and leave us in grave doubt when it should be used at all. If the tradition of this drug tempts you to its use in any form of vomiting, I beg to consign it to your charge with care, and trust that you will carefully use your own judgment in applying the drug where the least danger exists. In concluding my observations on the medical treatment of the bowel, I feel it my duty to say that the most severe cases that we meet in our daily practice are frequently beyond the reach of our medicines, when arising from locking of the bowel, and properly belong to the region of operative surgery for their relief."

RECENT ADVANCES IN ORTHOPÆDIC SURGERY.

IN surgery, as in the allied sciences, a gradual growth with occasional marked advances, counterbalanced by serious errors, has brought us to the present standpoint. But in no department has superstition, ignorance, and charlatanism retarded the progress to such a degree as in the special department of orthopædic surgery. Its advance has been marked by periods of activity followed by intervals of repose.

As in the history of amputations, in which perfection has been marked by three great achievements—the discovery of the tourniquet, ligature, and the antiseptic method—so progress in the treatment of club-foot has had its perfection hastened by important discoveries.

Hippocrates described these deformities, and Polybius handed down the record, but a long interval succeeded, and even in the time of Celsus, when every other subject was considered, this is not even mentioned, so that it was not until the middle of the seventeenth century that it again claimed attention, and the second impetus was given to the subject by Ambrose Paré. Following him came Severinus, Fabricius, Andry, and Du Verney, but nothing important was added to the subject until 1784, when Thilenius, a physician of Frankfort, successfully performed an open section of the tendo Achillis, and Venal, called by some the "father of orthopædic surgery," founded an institution in Orbe, Switzerland, and together they inaugurated a revival in orthopædy.

The impetus given by these masters was continued by such men as Stromeyer, Delpech, Rudolphi, Petit, Velpeau, Dieffenbach, Bonnet, and Guérin, but it was not until the full recognition of the grand possibilities of antiseptic surgery emboldened men to undertake procedures that before seemed impossible, not until the appearance of the osteoclast, the osteotome, the wrench, etc., and the performance of osteoclasis, osteotomies, redressement forcé, excisions, resections, etc., brought us into the midst of a new era—an era as decided as those of 1641 and 1784, and, we believe, equally, if not more, important. If we doubt this, we have but to look about us to witness the immense strides that orthopædic surgery has taken within the past fifteen years, and it was the advent of the antiseptic era that rendered them possible.

These advances are all in the direction of positive methods and certain results. In the operations for club-foot the resisting structures are unfolded and the foot retained in a corrected position until there is no tendency to relapse. This is accomplished by stretching, tearing, or dividing the contracted tissues. Thus, the methods of to-day may be divided into mechanical and operative.

The best instrument with which to apply force is undoubtedly the hand, and it has been shown recently (*Trans. Amer. Orthop. Assoc.*) that the force that can be safely applied is only a little short of that which would cause destruction of the soft parts. But this is often inadequate, and screw power is brought to bear through the mechanical devices of Morton and Bradford, or the wrenches of Thomas and Gibney. With these a powerful crushing force can be applied, which, with stretching and tearing, brings the foot into a corrected or over-corrected position.

Of the numerous operative procedures presented for severe and inveterate cases, the most important are combinations of tenotomy with subcutaneous or open incision, and osteotomies. Subcutaneous incision of all the soft parts on the inner side of the foot has the advantage of leaving the skin intact, but, combined with the danger of cutting the internal plantar artery and nerve, there is also an element of uncertainty in the tissues divided that does not occur in the open incision.

Strict antisepsis then has substituted for the subcutaneous operation the percutaneous method or open

incision of Phelphs and Hingston by which all the tissues which prevent perfect redressement—the skin, fascia, tendons, ligaments, etc., can be incised, and the wound be allowed to heal. That the operation is gaining ground one must infer from the increasing number of cases thus treated abroad, and the favorable terms in which it is spoken of by Schreiber, Rupprecht, and others. As performed by Nönchen, Cordua, Ph. Schede, Lauenstein, Albert, Billroth, and others, it is essentially the operation of Phelphs, and O. v. Büngner, in a recent contribution to the *Centralb. f. Chirurgie*, "Upon the Treatment of Congenital Club-foot in the Clinic of Prof. Volkmann, at Halle," reports twenty-one operations in fourteen cases, treated since 1884, ranging from four months to fifteen years, and commends the operation, all the cases healing without reaction and presenting beautiful results.

The division of the internal lateral ligament, as pointed out by Parker, is an important addition in certain cases, and deserves more general recognition than it has generally received.

The immunity from bad results under the protection of antiseptic covering has even led many beyond the bounds of propriety, and some dozen or more operative procedures upon the osseous structures of the foot have been advocated—the astragalus, talus, scaphoid, cuboid, the cuneiform bones, and the apex of the external malleolus have all been removed, and we cannot help thinking with Reeves, that these are the days of *les folies chirurgicales*, or as Erichsen has termed them, of *surgical audacities*.

There is, however, one operation which is likely to retain its position among accepted procedures for the relief of inveterate cases—astragaloid osteotomy. As described recently by BRADFORD in a paper before the American Orthopædic Association, the procedure is not difficult, and "the result is similar to that in Macewen's operation for knock-knee." An incision through the skin is made clear to the bone from the tip of the internal malleolus to the inner side of the first metatarsal, and the foot straightened as the metacarpal bone is separated from the malleolus. The scaphoid will be seen before the astragalus is encountered, if the deformity is great, and it will be first within reach of the knife in all cases. If the foot is still further stretched, the scaphoid begins to uncover the side of the astragalus, and the neck of the astragalus is seen; a small osteotome is placed upon the neck of the astragalus, to the distal side of the scaphoid articulation, and as in the Macewen operation, the neck of the astragalus is nearly or fully divided. The foot is then forcibly straightened, and the unchiselled portion of the neck of the astragalus is fractured.

With these means—forcible manual and mechanical restoration, tenotomy, subcutaneous or open incision, and astragaloid osteotomy—there is a certainty of curing club-foot never before obtained, and, as Bradford remarks, "In no branch of surgery can a cure be more confidently promised than in the treatment of club-foot."

Truly, we are to-day in the midst of a new era in orthopædic surgery, and the names of Macewen, Ollier, Gibney, Willard, Parker, Phelphs, Lorenz, and others, will characterize a period of surgical activity equal to any the world has known.

THE GROWTH OF THE BRITISH MEDICAL ASSOCIATION.

THE annual report of the Council of the British Medical Association presented at the Leeds meeting this week gives some interesting data concerning the growth of the Association. It calls attention to the fact that when the Association for the first time met at Leeds, in 1843, its membership was a little over 1600; twenty-six years later, when it met again in the same city, it had increased only about 2400; and now on its third visit to Leeds, after the lapse of twenty years, its membership has further increased by 8802 to a total of 12,897.

The marvellously rapid rate of growth in recent years of the membership of the Association is the direct result of, and has followed closely upon the advancement of the *British Medical Journal* to the position of the leading medical periodical of Great Britain, through the able editorial management of Mr. Ernest Hart and the active coöperation of a very large staff, such as only a great centre of medical activity like London can furnish. As soon as the *Journal* attained this position medical men all over the kingdom hastened to become in receipt of it by joining the Association. Thus the *Journal* has built up the Association to a large membership and to a position of widespread influence and power, and it has an additional circulation, outside of the Association, of between two and three thousand. Its present total circulation of over 15,500 copies is probably not exceeded by any medical journal in the world.

During the year the Association has expended fifteen hundred dollars on its library and two thou-

sand dollars in grants in aid of original scientific research. Its financial exhibit shows a net profit for the past year of over twenty thousand dollars. Altogether the Association presents a degree of prosperity, and is doing an amount of good work which is extremely creditable alike to its management and to the British profession.

The United States Hay Fever Association will hold its Sixteenth Annual Meeting on the 27th of August, at Bethlehem, N. H.

Dr. Kinyoun, of the Marine-Hospital Service, and some others engaged in physiological inquiry, requested the Mayor of New York City to allow some of the condemned dogs at the pound to be transferred to them for scientific purposes. The Mayor has duly considered the petition, and has also heard what the anti-vivisectionists have to say; he has rendered his decision, which is a refusal to give the dogs over to them in a living state. After the dogs have been drowned the students can have all they want: "hundreds of them for anatomy, but not one for physiology," is the Mayor's doctrine.

A fatal case of actinomycosis hominis has recently occurred in New York City. The case was that of a young man, who was well up to February last, but in April became very ill, with symptoms referable to the liver. At the autopsy the liver was found to weigh nine and a half pounds, and the size of the fungoid growth upon and within the liver exceeded that of the organ itself. His attending physician have, as yet, been unable to determine, to their satisfaction, how the disease in this case was contracted; they suspect that the fungus was swallowed with food or drink, and, taking root low down in the œsophagus, spread thence along the diaphragm to the abdominal wall and liver. The liver is rarely the seat of actinomycosis; in fact, the disease is not often found in any of the organs below the diaphragm, but when it is so found it is in most cases located in the intestine.

Dr. Alexander B. Mott, Professor of Clinical and Operative Surgery in Bellevue Hospital Medical College, died of pneumonia after a very brief illness at his country residence at Yonkers last Monday.

Dr. Mott was the fourth son of the late Valentine Mott, and was born in New York on March 21, 1826. He was graduated in medicine in 1850, and subsequently served as Visiting Surgeon to St. Vincent's and Charity Hospitals. At the outbreak of the war he accompanied the first regiments to Washington and organized their medical corps and served throughout the war, and was present at Appomatox Court House at the signing by Generals Grant and Lee of the articles of agreement to surrender. He was one of the original members of the faculty of Bellevue Hospital Medical College. He leaves one son, Dr. Valentine Mott.

Dr. James L. Cabell, Professor of Anatomy and Surgery in the University of Virginia, died at Overton, Va., on Tuesday, aged seventy-six. He was graduated in medicine at the University of Maryland, in 1834. During the war he had charge of the Confederate military hospital in Charlottesville. He was Chairman of the National Sanitary Conference at Washington during the yellow fever epidemic at Memphis, and subsequently was President of the National Board of Health. He was an accomplished physician, and a scholarly and courteous gentleman.

Job Kenyon, M.D., died of apoplexy, at Providence, R. I., on the 5th inst., at the age of sixty-eight years. He was born in Exeter, R. I. He was graduated in medicine at the Yale Medical School, in 1846. In 1862 he became Assistant Surgeon to the Third Rhode Island Artillery, then stationed at Hilton Head, S. C., but was compelled, on account of ill-health, to resign after a few months' service. From 1865 to 1869 he was Physician to the United States Marine Hospital, then located in Providence. In 1871 he was appointed by Gov. Padelford a member of the Board of State Charities and Corrections, in which office he continued until his resignation in 1884, rendering the State intelligent and efficient service. He represented the towns of Coventry and Warwick at different times in the State Senate. He became a Fellow of the Rhode Island Medical Society in 1854 and was its president for two years (1883–84).

Dr. Kenyon was a man of acute perception, excellent judgment, and untiring industry. His counsel was widely sought in consultation, both by physician and patient. He passed away while actually practising his profession, as he was attacked while in his office and fell to the floor unconscious just after he had dismissed a patient.

REVIEWS.

A SYSTEM OF OBSTETRICS, BY AMERICAN AUTHORS. Edited by BARTON COOKE HIRST, M.D., Associate Professor of Obstetrics in the University of Pennsylvania, etc. Vol. II. 8vo., pp. 554. Philadelphia: Lea Brothers & Co., 1889.

The second and completing volume of the American System of Obstetrics justifies amply the expectation aroused by the foregoing volume, and furnishes a most satisfactory exposition of modern obstetric science.

The "Diseases and Accidents of Labor" are discussed by Parvin in his comprehensive and facile manner. His treatment of hemorrhage and eclampsia—two subjects of great importance—is especially full and practical. Davis writes on the "Forceps and Embryotomy" clearly and concisely. The most recent views upon the use of instruments during labor are presented, with cuts of the instruments employed. The arguments in the choice of embryotomy and Cæsarean section are impartially given and embrace the latest statistics of various operators. "Premature Induction of Labor and Version" receive full exposition by Cameron, of Montreal. His illustrations are especially good, and his descriptions embrace the procedures most often adopted in foreign maternities.

The topic "Cæsarean Operation, Symphysiotomy, Laparo-elytrotomy, and Laparo-cystectomy," at once suggested Harris as the author most fit to treat it, and the volume is enriched by an accurate and scholarly article from his pen which fully covers all known to the date of writing on these subjects. It is interesting to note that a practical consensus of opinion as to the indications for and relative place of the modern Cæsarean operation exists between the writers of the different articles in this volume which touch upon these points; the extended discussions on this subject, which have gone on for the last few years, have cleared up much that was undecided, and formed an opinion which may guide the practitioner in difficult cases.

Garrigues very sensibly styles his article "Puerperal Infection," and gives a clear and exceedingly practical exposition of the subject. It would be well if Garrigues' plea for his title were allowed and the misleading term "puerperal fever," banished from obstetric nomenclature. His well-known method of antiseptic treatment is fully described and illustrated. The much-vexed topic "The Etiology of Puerperal Fever," receives thoroughly scientific treatment at the hands of Ernst. His conclusions are of such clinical interest that we give them: Puerperal fever is not a specific process, but only one form of an infectious wound disease, always exogenous in origin. It is produced in all cases by living ferments, either by destruction of tissue or mechanical obstruction, or indirectly by production of leucomaines.

Hirst contributes a useful study of "Some Complications of the Puerperal State Independent of Septic Infection," which embraces many conditions frequently met by the practitioner and of great practical interest. The article is illustrated by characteristic temperature curves.

The selection of a neurologist to write upon "Insanity and Diseases of the Nervous System in the Childbearing Woman" is more than justified by Lloyd's interesting article on this subject. "The Newborn Infant" receives very comprehensive medical and surgical attention by J. Lewis Smith and Stephen Smith, of New York, these articles being among the most valuable in the volume. The volume is closed by De Schweinitz, who contributes an interesting account, with illustrations, of the "Congenital Anomalies of the Eye."

SOCIETY PROCEEDINGS.

THIRD CONGRESS OF THE GERMAN SOCIETY OF GYNECOLOGY.

Held at Freiburg, June 12, 13, and 14, 1889.

(Specially reported for THE MEDICAL NEWS.)

(Continued from page 161.)

TWO CASES OF RUPTURE OF THE UTERUS.

DR. KEHRER, of Heidelberg, presented anatomical specimens of a very rare case of uterine rupture which took place in the posterior wall of the uterus. The walls in this region are very thin; this uterus also is divided by a band which reaches down to about the level of the inferior segment of the organ. This case had a contracted pelvis and version was attempted; but on account of this band, a false direction was taken which resulted in rupture of the uterus. He performed Porro's operation and then tamponed the abdominal cavity with iodoform gauze, and the patient was cured without febrile reaction.

DR. WIEDOW, of Freiburg, presented a case in which he had performed Porro's operation; he had to deal with a case of spontaneous uterine rupture in a contracted pelvis; the fœtal sac had penetrated into the abdominal cavity. The patient was cured without accidents.

PLASTIC RESECTION OF THE SACRUM.

DR. WIEDOW presented two cases in which he had done excision of the sacrum. He made a V-shaped incision, the rectum was detached and the sacrum excised with the chain saw up to the periosteum; in this manner he obtained a very extensive operative field. In the first case he had to deal with a carcinoma of the neck of the uterus, in the second with a pyosalpingitis.

DR. HEGAR said that this method allows the surgeon to see exactly what he does; one can see the uterine and utero-ovarian arteries beat under his eyes, and they can be easily ligated, while by extirpation of the uterus *per vaginam* one works entirely in the dark.

ON PERINEORRHAPHY.

DR. SONNTAG, of Freiburg, presented ten women who had been operated on by the methods of Hegar, Freund, Simpson, Tait, Sänger, and Martin. It is not of great importance that the preference should be given to the method of Freund or to that of Hegar; but he thought, however, that in complete rupture of the perineum the method of Freund has the advantage of preserving the posterior column of the vagina, and so consolidating the perineum. In cases of incomplete rupture all methods give good results. In prolapse of the vagina there is an advantage in employing Hegar's method. Out of 256 patients operated upon by Hegar's method in the past seven years, he only had one failure, and in this case an abscess formed in the anterior portion of the wound. Out of six patients who were operated upon by Freund's method, four of them being complete ruptures, one a prolapse, and the other an incomplete rupture; only one

case did not unite by first intention. Simpson's procedure has given him good results in prolapsus; it is not more nor less rapid than Hegar's method, but it is excellent to produce a very strong recto-vaginal wall. Out of eleven cases of complete prolapse he had excellent results in ten cases, and in one case secondary union. In tha cases operated on by Tait's method he had obtained less satisfactory results. He thought that in prolapses, elytrorrhaphy followed by perineorrhaphy is not so reliable as colpoperineorrhaphy.

Dr. Sänger, of Leipzig, had used the method of perineorrhaphy by flap in seventy-one cases of perineal rupture. In twenty-five cases perineorrhaphy was preceded by anterior elytrorrhaphy, in two cases by elytrorrhaphy, and in twenty cases both these operations were employed. In all cases he obtained, nearly without exception, a reunion by first intention.

For sutures he employed, in all cases but two, silver, the extremities of which were united by a shot. This process will repair all perineal or vaginal ruptures, but its real advantage is seen in perineal ruptures with complete tear of the sphincter ani. The advantage of perineorrhaphy by flap is to preserve cicatricial tissues and to utilize them for strengthening the perineum. The rapidity of the cure by this process is due to the fact that the skin of the perineum is brought into apposition with the labia majoris, and we know that the union of skin is much more rapid than the union of mucous membrane.

Dr. Küstner, of Dorpat, said that tears are usually produced on one side only, and in that case he did not see the advantage of the method by flap; he thought that we ought to choose the method most appropriate to the case which presents and try to restore the parts as near as possible to their natural condition. By Hegar's method, with time, there is produced a depression in the level of the perineal sutures, which is the result of the forced coming together of the lateral parts of the perineum.

Dr. Hegar said that by complete rupture of the perineum, he meant a rupture with a complete tear of the recto-vaginal wall. Sänger has a very large series of complete ruptures of the perineum. He wondered whether he, by complete rupture, meant the same. The method by flaps cannot restore the natural parts; he unites flaps which were not formerly in relation to each other, and this great displacement in a perpendicular direction determines a great tension of the perineum. By the other methods patients will rise after twelve days. Kustner says that by the speaker's method a depression on the perineum is left near the vagina; he found that this depression does not really exist. If one is not careful it can be produced by the vaginal touch; but if one practises at the same time the rectal and vaginal touch, he finds that the depression does not exist.

ON EXTRA-UTERINE PREGNANCY.

Dr. Veit, of Berlin, said that, from an operative point of view, we must divide extra-uterine pregnancies into the pedicellated and non-pedicellated forms; those in which we can completely extirpate the sac, and those in which we cannot. During the first months extra-uterine pregnancy is easy of operation. Extra-uterine ovarian gestation is liable to the same operations as other ovarian tumors; in extra-uterine pregnancy of the tube, rupture of the sac is to be feared; this rupture can be unilateral, and can take place between the layers of the broad ligaments; in such a case there is no danger during the first five months of gestation. For the operation for extra-uterine pregnancy in the first months, the operative procedure consists in ligating the two extremities of the Fallopian tube and the broad ligaments, and then excise; in the majority of cases the diagnosis can be made, but not very absolutely; the careful examination of the uterine mucous membrane to see whether or no there exists a decidua is very important. The symptoms of rupture of the sac are those of labor, hemorrhages which can produce themselves during the life or after the death of the embryo; the pains are not always constant. By the touch, one feels on one side of the uterus a tumor which is easily recognized to belong to the tube, of soft consistency, without fluctuation or tension. There might, however, be some tension in the sac, with a hard feeling when there is a clot. The decidua can detach itself in the third month and give rise to hemorrhages without the embryo suffering from them.

As for the treatment, we have electrolysis, morphine, or an operation. He did not attach great importance to electrolysis; it gives pain, and may be the cause of rupture of the sac. Morphine is an excellent palliative treatment which brings on absorption of the ovum, but notwithstanding the results obtained by injections of morphia into the fœtal sac, he preferred laparotomy.

Tait has had two cases of death out of forty-three cases of extra-uterine pregnancy; in those two cases he had to deal with a case of rupture of the fœtal sac. The speaker had operated on fifteen extra-uterine pregnancies, twelve without rupture of the sac, three with rupture of the sac. Injections of morphine in the beginning of extra-uterine pregnancy is dangerous, for the ovum can rupture at the moment of the injection, and out of his three cases of rupture of the sac he had saved only one patient; in those cases of rupture one feels nothing in the abdomen; and, on the other hand, it is a dangerous proceeding to compress the little tumor, as we are liable to break it.

Dr. Werth, of Kiel, said that the passage of the ovum between the layers of the broad ligaments can take place without producing a solution of continuity in the tissues. He had observed a case in which the fœtal sac had passed through the broad ligaments without there being rupture or hemorrhage. Schuchardt had published a case in which the placenta penetrated through the connective tissue of the broad ligaments and determined a bloody infiltration under which the fœtal sac was buried. Olshausen had found such a case, which he operated upon six days after the rupture of the sac and obtained a living child.

In the last few years he had had to treat nine cases of extra-uterine gestation, with a mortality of 22 per cent.; the non-pedicellated extra-uterine pregnancies are very difficult to remove entirely, yet one cannot leave in place the embryonal sac in a state of putrefaction.

When it is necessary to operate, which is the best method to be used, laparotomy or the vaginal method? Hermann prefers elytrotomy; when there is pus or putrefaction he removes the placenta of the fœtal sac. In a case of intra-ligamentous pregnancy, Breisky succeeded in extirpating the fœtal sac, and he obtained a living fœtus; it is well to remove the placenta at the same time as the fœtus. One must not try to obtain a living child, but rather think of the dangers to which the mother is

subjected. He considered dilatation of the uterus as a radical method to destroy the fœtus.

DR. OLSHAUSEN, of Berlin, had operated lately on five cases of extra-uterine pregnancy, two in which the normal term of gestation had passed, and three in the last month of pregnancy. He obtained two living children and one dead. Twice he succeeded in removing the placenta, and once he made drainage; twenty-eight days after the operation the placenta became detached; in this last case, the child was free in the abdominal cavity and the woman had had pains. He, at first, could not find the membranes; finally, he found them with the placenta in Douglas's cul-de-sac, and he ligated them all together. He thought that in cases of extra-uterine pregnancy one always finds a decidua, which he must not mistake for a menstrual decidua, which is only composed of fibrin. He had seen a woman who for years would lose at each menstrual period such a membrana decidua.

UTERINE RETROFIXATION.

DR. FREUND, of Strasburg, said that in grave cases of prolapse of the uterus and vagina, complicated with hernia of the intestine, no special operation had been proposed up to date. On the other hand, the methods employed, such as colporrhaphy, perineorrhaphy, extirpation of the uterus, ventrofixation of the uterus, etc., have all proven to be insufficient. In one case of this kind, after having made a large opening in Douglas's cul-de-sac, he sutured the posterior part of the uterus to the peritoneum situated above the promontory, in the neighborhood of the utero-sacral ligaments. He made his sutures below the utero-sacral ligaments, so as not to involve the rectum. He uses this method in deep retroflexions with a large cavity of Douglas. This operation is a rational one, and has its place beside ventrofixation.

ON THE MECHANISM OF ROTATION IN RIGHT OCCIPITO-POSTERIOR POSITIONS.

DR. FROMMEL, of Erlangen, said that he had been trying to find out whether rotation of the head preceded that of the trunk, and by giving chloroform he had observed that occasionally the head turns first, and finds itself in front, when the trunk is still behind.

DR. SCHATZ, of Rostock, thought formerly that rotation of the trunk preceded that of the head, but he now thought that the head always turns forward first.

DR. HOFMEIER, of Würzburg, saw at the Berliner lying-in clinic, a woman who during labor kept the sitting posture; in this case he observed that the trunk first turned forward.

DR. OLSHAUSEN, of Berlin, still believed that rotation of the trunk precedes that of the head.

DR. SCHWARZ thought that there are cases in which rotation of the trunk brings about that of the head.

ON SUTURE IN CÆSAREAN SECTION.

DR. VEIT, of Berlin, lately had performed Cæsarean section on a female monkey in the last stages of pregnancy. He sutured the uterus by separate sutures; at the end of five days he examined the uterine wound and found that the peritoneum had united.

As to the favorable moment to perform the Cæsarean operation, is it to be made when the woman has no pains? He had lately operated upon a woman without her having any pains, and he had not met with atony of the uterus.

DR. BAR, of Paris, had operated in similar conditions, with the same success. Cases have been published where the uterine incision had been made without there being any pains, and in which great hemorrhages occurred from atony of the organ. He thought that the operation ought not to be undertaken before the pains are clearly present.

DR. SÄNGER, of Leipzig, said that the uterine wall of the monkey is very thin and cannot be compared to that of the human uterus. He thought that we ought always to liberate the peritoneum on the borders of the uterine wound so as to bring the two layers in contact.

DR. LEOPOLD had had three cases of death after Cæsarean section, and he observed each time that the peritoneum had united, although he had not dissected this serous membrane.

As to the moment at which the operation is to be performed, he thought that we must never interfere without there being well-characterized pains. He had lately operated upon a woman, who had for six hours slight pains. This woman died from hemorrhage by uterine inertia, yet she had had a very powerful contraction when he removed the rubber band.

ON EXTIRPATION OF THE UTERUS BY ZUCKERKANDL'S METHOD.

DR. FROMMEL, of Erlangen, said that the extirpation of the uterus by the vaginal method is often very imperfect. For this reason Zuckerkandl, of Vienna, proposed to extirpate the uterus through the recto-vaginal septum. To do this, a curved incision starting from the ischium is made, going between the anus and coccyx, the rectum is then freed from its attachments and it is lifted upward; the rectum can be liberated with the fingers alone, no instrument being necessary. In this manner, a very large wound is obtained, through which one can introduce the fist into the peritoneal cavity; the arteries are easily ligated and the large wound allows a free access to the uterus and permits the removal at will of all carcinomatous tissues; the bladder is easily separated from the fundus of the uterus. He thought this operation was quite practicable and of great usefulness in difficult cases; it is also indicated in retro-uterine abscesses.

ON EXTIRPATION OF PELVIC TUMORS BY PERINEOTOMY.

DR. SÄNGER, of Leipzig, said that by the name perineotomy he meant the exposure of the ischio-rectal fossæ by the peritoneum for the removal of cysts, hematomas, exudates or other tumors having their seat in the connective tissue and Douglas's cul-de-sac. A year ago he did such an operation on a woman aged forty-two years, suffering from a retro-rectal and recto-vaginal dermoid cyst. This woman had been obliged in her last six labors to have the help of a physician on account of the great development of the tumor. He made an incision of three inches, starting from the middle of the part separating the right labia majora from the anus and extending beyond this orifice; he penetrated into the pelvis, where he found a cyst having the size of a child's head; this cyst was independent of the ovary. The patient was cured perfectly. Only ten cases of the kind has he been able to find in the literature of the subject.

(To be concluded)

PHILADELPHIA ACADEMY OF SURGERY.

Stated Meeting, June 3, 1889.

J. Ewing Mears, M.D., in the Chair.

Dr. F. H. Gross reported a case of

RUPTURE OF THE QUADRICEPS TENDON

above the patella of the left leg. The injury was received March 2d, and the case at once came to the hospital. There did not seem to be any opportunity for applying sutures. There is a fair degree of usefulness, mainly through the accessory tendons of the vasti muscles. It occurred to him that it might be advisable to transplant the lower attachment of these tendons to the region of the ligamentum patella.

Dr. Nancrede had seen two such cases. One was in private practice, and there was admirable functional result. In the second case, also, he presumes that the result was good. The first case was caused by the tongue of a heavy wagon striking the tendon and cutting it subcutaneously.

Dr. William Hunt desired to record an

ANOMALY OF THE CHEST ORGANS.

which he recently met with at the Pennsylvania Hospital. A young woman looking very miserable and phthisical was admitted with necrosis of the manubrium of the sternum with a sinus leading to the diseased bone. She was in such a weak condition that before operative procedure could be resorted to she died.

On opening the chest it was found that the right lung extended all the way across to the left side, and completely filled the upper and lateral parts of the left cavity. The mediastinum and its contents were pushed out of the way. The heart was held to the left wall of the thorax by adhesions of the pericardium. The left lung was practically gone. The remains of it were not as large as the fist, and there was no breathing tissue in it whatever. There was a vomica present at the apex of the right lung, but whether tubercular he could not say. He thought that in this case the most acute auscultator would have been deceived and would have naturally thought, when listening over the left chest, that he heard the murmurs of the left lung. It might be that one percussing across the front of the chest from right to left, and noticing the continued resonance, would have a suspicion of the condition present. He had never met with a similar case.

Dr. Nancrede called attention to an interesting case bearing on the

TREATMENT OF ACUTE INFECTIVE OSTEOMYELITIS.

It is not often that the surgeon has an opportunity to treat these cases in the early stages, for they are usually found in the medical wards under the head of rheumatism, typhoid fever, etc. We constantly meet with the results of such attacks when they have been partial and the patients have recovered. French surgeons are of the opinion that in the better classes with good surroundings, the disease is often recovered from, but we all know that in the average run of hospital cases among the lower classes, the disease is very often fatal. He could only recall a few cases in his twenty years connection with the Episcopal Hospital, in which the cases were seen by the surgeon in the earlier stages. One was not diagnosticated by the surgeon in charge, and the patient died.

Another case was that of a child sent in practically dying, who for a week or ten days had been treated outside for rheumatism. He made the freest possible incision and tried to treat it antiseptically. That was fourteen years ago. Since then several Russian surgeons, Mr. Keetley, and the French surgeons have called attention to the benefits of free opening of the bone and the removal of the medulla. He had been for some time watching for such a case.

A week ago his attention was called by his Resident to a boy in the Episcopal Hospital who was supposed to have erysipelas of the leg. He had been examined by a medical colleague, who thought it was a sprain. He had been treated outside for rheumatism. He found the temperature between 102° and 103°; the boy delirious, and evidently very ill. He examined the limb and recognized what he considered to be osteomyelitis. He examined it with an exploring needle and found the bone bare in all directions, and pus oozed up through the minute puncture in a steady stream for hours, showing the enormous pressure it was subjected to. Sixteen days before, the boy, who was seventeen years of age—in what has been called the epiphyseal age—had twisted his foot slightly in jumping from a wagon. The next day he complained of what was supposed to be rheumatic pain. On the third day he continued to work, but on the fourth he became ill enough to go to bed, and on the sixth he was brought to the hospital. He saw him on the seventh day. Three hours elapsed before he could gain permission to operate, and in that time the disease progressed upward at least two inches. He exposed the tibia, white and totally stripped of periostium from the lower epiphysis to within three inches of the upper, and trephined over the upper portion of the bared shaft with a large trephine, striking living medulla, although the external surface was white and apparently dead. He then trephined as close as possible to the lower epiphysis, when pus escaped as soon as his trephine pin pierced the compact layer. He trephined two inches above and cut away the intervening bone. He then removed the medulla, which was gray and looked as though it were sloughing in some places. He again trephined higher up and cut the bone between. He also cut away still further, opened a second abscess and cleaned out the medulla. After thoroughly removing the medulla he packed the cavity. The temperature dropped 4° in two hours. To-day it is normal, and the boy is sleeping well and feeling comfortable. He thought that the greater part of the bone would be saved. The boy's life is certainly saved.

He thought that the usual teaching of our surgical text-books is that in such cases the limb should be amputated, although some of them refer incidentally to the operation of trephining, and the removal of the medulla, and say that possibly that may answer. He believed that this will always answer if it is done effectually. He thought that no limb should be sacrificed until this is tried. It is so rare that the surgeon sees these cases at an early period, that he thought it worth while to report this case.

(To be concluded.)

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, June 20, 1889.

THE PRESIDENT, ALFRED L. LOOMIS, M.D., IN THE CHAIR.

DR. A. JACOBI read a paper entitled

NOTES ON THE BAKING OF BACILLI.

He said that of late the inhalation of dry hot air in pulmonary tuberculosis had received considerable attention. Having made some remarks strongly condemnatory of all patented apparatuses and processes in medicine, he said that the patented apparatus of Dr. Louis Weigert, who is said to have been graduated in New York, but is now a resident of Berlin, was not very perfect in its mechanical construction, and was at the same time very expensive.

The attention of the profession was first directed to the use of dry hot air in consumption by Dr. Louis Halter, in an article published in two numbers of the *Berliner klinische Wochenschrift*, in September, 1888, and accompanied by a drawing of an apparatus which he had devised. His attention was first drawn to the matter by the exemption of lime-kiln workers from phthisis, and his observations, extending over a period of fifteen years, were made in Westphalia, where this disease was very prevalent among the general population. The air about the ovens is quite dry and very hot, the temperature usually ranging from 122° to 158° Fahrenheit. Such air must, therefore, be for the most part free from tubercle bacilli, which, it has been established, die at a temperature of from 140° to 149° F. The air about the lime-kilns is also greatly rarefied, and it has the effect, in the case of new operatives, of increasing the body temperature two and a half degrees above the normal, while the pulse is raised from 120 to 160, and the respirations to 20 to 30 to the minute. Old hands, however, perspire very freely, and feel perfectly well.

Another paper on the inhalation of dry hot air in phthisis was also published in the *Berliner klinische Wochenschrift* in September, 1888, by Dr. E. Krull, and this was likewise accompanied by a representation of an apparatus devised by the author. It was not until December, 1888, that Dr. Louis Weigert published an account of his apparatus in the New York *Medical Record*, and in his communication he made no mention whatever of the articles by Drs. Halter and Krull. About the same time he also exploited his apparatus in the public press; proclaiming that consumption was entirely curable by his treatment, and that he was the equal of Koch by reason of his great invention.

Dr. Jacobi then went on to say that he had used the Weigert apparatus to a considerable extent in his wards at Bellevue Hospital, and that the results had not been at all satisfactory. It was true that in many of the cases more or less improvement was noted while it was being used; but it was a well-established fact that patients that came to the hospital with phthisis, except the disease was in the last stages, improved for a time after entrance, on account of the nutritious diet and the rest and freedom from worriment afforded them. He found by repeated observations that the temperature of the air to be inhaled from the apparatus was always many degrees lower by the time that it had passed through the tube conveying it to the mouth of the patient than it was when it left the cylinder in which it was heated. In addition, the temperature of the air was further reduced in the pharynx and trachea, and when the proportionately small amount remaining finally reached the great volume of the blood, and was diffused over the extended surface of the lungs, it was still more cooled down. The expired air was, in fact, warmer than the inspired air. When it was remembered, furthermore, that the bacilli were located and multiplied deep in the tissues, it seemed hardly probable that they were disturbed at all, it was not even likely that the soft lung tissue could be heated above normal, while neither the pulse nor the general temperature of the body showed any alteration. It was evident, therefore, that in order to destroy the bacilli, something more was required than the inhalation of hot air in an ordinary room. The temperature of the apartment in which the inhalation was given ought to be at least 105°. The temperature to which the men working at the lime-kilns mentioned by Halter were subjected, varied from 106° to 158°.

Both the hot inhalations and the hot room, however, find their contra-indications in all cases where the patients were weak or liable to hæmoptysis, and could only be employed with safety, therefore, where the patient was comparatively robust. Dr. Jacobi believed, consequently, that this method of treatment should be resorted to only in the very earliest stage of phthisis. In the cases in which he had used the hot inhalations, other causes, as he had mentioned, would account for the improvement noticed, where any improvement followed. In a few he found it difficult to control the cough excited by the treatment, and in two instances it caused so much vomiting, with other disagreeable symptoms, that the patients were decidedly better after stopping the inhalations.

Then followed a

PRESENTATION AND DESCRIPTION OF THE PLANS OF THE NEW ACADEMY BUILDING,

by Mr. R. H. Robertson, the architect. The lot on Forty-third Street, near Fifth Avenue, upon which it will stand, is seventy-five feet wide and one hundred feet deep, and it is designed to have the structure as complete as possible in every detail. It will be five stories in height and will also have a gable story, and the materials used in the front of the building will be brick and Long Meadow stone, both rock-faced and dressed. The kitchen and janitor's apartments will be in the basement. On the first floor are the committee-room, coat-room, and meeting-room (the latter 36 x 26 feet) in front, and in the rear a large assembly room, 57 x 42 feet, and a dining-room 31 x 26 feet. These two rooms are separated by a rolling partition, and they can be thrown into one at any time when required for large meetings or a largely attended dinner. One and a half stories are taken for this part of the house, and the rooms are twenty-six feet in height. On each side are air-shafts, and by means of a glass arch a flood of light is let in at the end of the rooms. The half-story in front of the building, which is eleven feet high, is to be used for committee-rooms, etc. The next story will contain the reference library and the stack-room, which occupy a story and a half. In the front there will also be three reading-rooms of less height. The full capacity of the stack-room will be for 230,000 volumes, to accommodate which there will be three tiers

of stacks. At first, however, but a single tier will be necessary. The next floor will be taken up by four section rooms, each with an ante-room and specimen or apparatus-room, and accommodating respectively 160, 125, 125, and 110 persons. On the top story, which will not extend over the whole of the building, will be a microscope-room and the librarian's apartments, and the rest of the space will be devoted to an open deck, which will probably be fitted up as a summer garden.

THE PRESIDENCY OF THE NEW YORK BOARD OF HEALTH.

DR. WALTER MENDELSON introduced the following resolutions:

Whereas, The Board of Health, being a department of the city government in which every member of the community is most personally and vitally interested, and being one where it is absolutely necessary for true efficiency that the presiding officer be acquainted with sanitary science and have a knowledge of the laws of health and of diseases; and,

Whereas, The medical profession, as guardian of the health of the members of the community, is being brought into almost daily contact with the workings of the Board of Health, and is therefore especially interested in its efficiency; and

Whereas, The Mayor of the City of New York has recently appointed to the Presidency of the Board of Health one whose previous experience no wise justifies the belief that he is at all fitted to assume the grave responsibilities of the office intrusted to him; therefore be it

Resolved, That in the opinion of the New York Academy of Medicine, the appointment of any one not specially qualified is fraught with possibilities of the gravest danger to the public health; and, furthermore, that the Academy of Medicine, having at heart the public good, urges the Mayor to reconsider the appointment made, and, after due consideration with those acquainted with the duties of the office, make a new appointment better suited to the important nature of the department.

On motion, the resolutions were referred to the Council of the Academy.

The Academy then adjourned until the first Thursday in October, and the exercises were concluded with a collation and social re-union.

CORRESPONDENCE.

A WINTER VACATION TO THE WINDWARD ISLANDS.

II.

OUR voyage down the Islands was the perfection of ocean travel. The "Barracouta" steamed by night and laid in port in the daytime, discharging at each place the packages of pork, flour, cheese, and various other things that sustain the life of man. The States feed the Islands, but that is all we do for them. They will have nothing else of us, as we bear a bad reputation among them. A planter told me that the freight on an 80-horse-power boiler was $500 from Glasgow. "Why did you not get it from the States at a less price and at half the freight charge?" I asked him. "Oh!" he said, with the air of a man who was stating a fact perfectly well known to me, "you do not make them so good or strong in the States." A merchant at Trinidad informed me that he formerly bought cotton goods and prints from us, but he was obliged to stop trading because we did not pack our goods securely, while the cases made in England were strong and did not break open and expose the contents. I am unable to conceive of any better proof that manufacturers who are nursed on high tariff become careless and bad workmen. We have one product that murderous legislation cannot touch—our food products. We can feed the world; but even here our "policy" has laid its crushing hand. Our tariff methods have swept our merchant navy from the seas, and all that we export has to be carried in foreign bottoms.

Meanwhile we were steaming on our way to St. Kits. The Caribbean Sea was as gentle as a dove, and flashed in the sunlight with a deep prismatic blue. We were gliding past islands that laid like gems upon the moving sea; some near, some far, all wrapped in purple mist. At one time we had in view St. Martin, St. Bartholomew, St. Eustatius, and Saba. The haze that laid upon the sea-line hid the bases of those mountainous islands upon which they seemed to float as thin as mist. We passed close under the southern end of Saba, the ship under half speed, as this is one of the sights of the Islands. Saba is a mountain rising in a vast precipice upon every side to the central mass, nearly 4000 feet high. A few red-tiled houses were huddled together here and there, some of them hanging on by their eyelids, as it were, to the edges of the cliffs, with nothing beneath them but the air and the crashing surf. The higher peaks were shrouded in the clouds, fragments of which clung to the sides and drifted down the gorges. We were so far away that we could see the silver lining to the clouds. Masses of vapor were piled up against the sun in dazzling whiteness, making the green gorges luminous in the creeping mist. On the side turned from the light, there was inky blackness with slanting streaks of rain, as though Saba in mountain, precipice, and riven glen had turned her face from the sun and wept in darkness. The effect was weird and strangely beautiful. I gazed as it receded from us until my eyes ached, while the island became a mere film of color on the distant sea.

Saba is a Dutch possession, with a scanty population, cut off from the fellowship of man. Strange to say, the industry of the island is ship-building. The graceful little schooners of sixty, or a hundred tons, so frequently met with among the Islands, are built here and lowered down the cliffs with ropes. It is a paradise for the doctor. He is the great man of the village. All who meet him take off their hats, and when a goat—the only animal on the island—is killed, a choice bit is always sent to him. We saw Saba on our return voyage in the glare of an afternoon sun and without the magic of its clouds and purple mist. It appeared naked and hideous. Paths could be seen to zigzag up the face of crazy-looking cliffs; here and there a few houses were perched upon bare rocks that quivered in the heat. It looked more fit for the abode of the damned than that of poor living humanity.

Had we seen St. Kits first we probably would have found nothing to criticise; but we had seen St. Croix and had fixed our standard of insular perfection. We set up the camera in various places about Basseterre, as the town is called, but the town was too English and conventional to be picturesque.

Night again found us steaming down the Islands over a gentle, phosphorescent sea. The trade wind was blowing from the northeast as steady as though manufactured by machinery. Nothing could give a more perfect example of earthly comfort than these nights at sea. We all studied astronomy under the stimulus of strange constellations. Orion and the Southern Cross were always subjects of interest; and which was the true cross and which the false one was forever being discussed and never settled. All the stars shone with great brilliancy, and owing to the excess of moisture in the air, twinkled like flash-lights. Venus ruled the sky, as the moon rose late, and was exquisite in her radiance. She came up about dark, and from then until near the zenith, she trailed her way over the restless water in a line of silver reflection that was lost in the faintly luminous mist that closed in the sky-line like a pathway from earth to heaven. A thing that one misses almost with a sense of personal loss is the absence of our northern twilight. Here the sun goes down with a quick burst of glory, and by the time the last segment has dipped below the sky-line night has closed down and blotted out every fragment of color from the western sky.

In the morning we were in port at Antigua. The town and bay were beautiful. Masses of irregular hills and cone-shaped mountains enclosed the bay. We were obliged to cast anchor about three miles from the shore, and had a rather rough passage in the boats of the negroes that lay about the steamer clamoring for passengers. Antigua is one of the oldest settled of the English Islands. The town, like those in most of the Islands, had little to attract us, and we made it a custom to hire carriages and ride into the interior. Here I remember we visited an old sugar estate conducted on a method of one hundred years ago. The motive power was a windmill; the rollers being placed below in the circular stone tower that carried the sails. Surrounded by palms it made a most exquisite picture, and I succeeded in getting a good negative of it. If the wind slacked while the rollers were choked with cane, the hands sat down and waited for the wind.

Everything about the place was on the same primitive model, yet the owner was quite content, caring nothing that the next estate, run by a rich company, had an 80-horse-power engine, vacuum pans, and a centrifugal drier. He was quite a young man, but he was an antique, a specimen of a race fast disappearing—the Creole English. He was thin to emaciation, dark as a mulatto, but every line of face and form indicated that he was pure white. There was a lethargic droop to the man that typified the hopeless struggle against fate that his race is making all over the world under hostile climate and environment. Among the hands about the sugar house we saw a magnificent specimen of a negro girl, who, in contrast to Mr. F., demonstrated the inexorable laws that govern the race-distribution of man. Under the conditions in which the white race exists in the tropics, there are developed forces which inevitably tend to extinction. It required just four generations to reduce the white man to the state we found him in. By the side of this decayed specimen of a noble race stood this magnificent girl. She was not more than half clad, revealing a skin as fine as silk, beneath which the slender muscles, hard as iron, played like serpents. Her waist was almost small enough to span, with a grand swell to her hips, tall, and straight as a bamboo, with a graceful sinuous movement as she raised a large tub of sugar to her head and carried it off with the ease of a trained athlete. Her shoulders and bust were splendid, modelled like an antique bronze. She was an emotion in ebony. Mr. F. told us that his sugar boiler, a white man, had taken her.

Here on this old plantation we have the whole story of the West Indian problem of to-day told with the force of a parable. The extinction of the white race, the exuberant vitality of the negro and the growing curse to the population, the negro half-breed. All these beautiful islands are in a state of material decay, and striking back, as the breeders say, into barbarism. England does not know what to do with them. She is trying the experiment of self-government, and if she succeeds it will not be many generations before we have the story of Hayti down the Islands to the South American coast. The negro under his natural climatic conditions cannot govern himself without drifting back into savagery.

Antigua is one of the most beautiful islands in the chain. The mountains are bold and precipitous, giving an exquisite sky-line as you approach it from the sea. Its fertility is not exceeded by any of her sister islands, so that we had here a profusion of beauty in tropic coloring and foliage. It was a matter of regret among us that the inexorable demands of trade obliged us to leave with only this glimpse of Antigua; but the next day we were more than repaid when morning found us lying snugly at anchor off the quaint old town of Plymouth, with the wonderful mountains of Montserrat casting their solemn shadows over us. Into these mountains we could gaze through the defiles which penetrated their rugged sides. The principal peak, ages past, had suffered an enormous fracture into its side which gave us a view of what appeared the interior of a crater. It appeared nearly inaccessible, and with the clouds, black and threatening, twisting over the rugged edges of the abyss, one never grew tired watching it and silently questioning the mystery of its depth.

In this little island there were enough of mystery and hatred hidden in its old-time history to populate a world. Montserrat was an English penal colony to which she deported Irish patriots after the "forties." Here they were let out to the planters and labored on the sugar estates. But time works its own revenge—to this day it is an Irish island. The Murphys, O'Briens, Sullivans, and other good, old names are heard everywhere, while the owners of these names are of all shades of color, ranging from the pure white of the Celt to the dull black of the African.

Plymouth is a walled town, and although the old fortifications are fast falling into ruins, enough remains to show that it was well able to take care of itself in the freebooting, buccaneering times. Every old house appeared to be a fortress, standing in the midst of a garden enclosed by thick stone walls. Between these walls ran irregular narrow streets, paved with large, flat stones, and overtopping them and shading the way were forests of palm, cocoanut, and breadfruit trees, broad-leafed plantains and weird, snake-like cacti. One of the streets near the landing was so quaint with its battered old walls, the palms and the broad leaves of the banana leaning over from the gardens within, and here and there a tower or picturesque gable, that I went back to photo-

graph it, and found the sun shining directly into my lens. I again visited the spot on my return, and had the good fortune to get an excellent negative.

Captain Hubbard, who always had the pleasure and comfort of his passengers in his care, gave us a picnic in a woods about two miles from town. We could secure carriages for the ladies only, and most of the gentlemen were obliged to walk. I never walked so far before under as hot a sun, and felt quite proud that I suffered as little as any one in the party. A thermometer went up to over 100°, but we would not allow the owner to state the exact figures for fear of the moral effect, as one of the party said. On the whole it was a very enjoyable affair. Several young English creole ladies joined the party. They were beautiful and well educated, with a very refined manner. I noticed the peculiar accent with which they spoke English. A very broad sound is given to the vowels, the words are drawled with something like an Irish brogue. This is to be noticed throughout the Islands, but its best examples are to be met with at Montserrat. We again at nightfall steamed away, and I shall never forget the night on deck after Montserrat. It was too enjoyable to lose any of it by turning in below, and nearly all the party stayed up till the small hours.

One of the sensations of this voyage was that of enchantment. At night you went to bed in one country and in the morning found yourself in another without any sense of a journey from place to place. Each island had its individuality. Customs, manner, accent, scenery, and products all gave a measure of difference sufficient to realize that you were among another people in another land. A vivid novelty, a feeling of expectancy, kept the mind alert and the body active without fatigue. During the evening Mr. H., a merchant of large enterprise and thoroughly familiar with the West Indies, and especially with Martinique, told a story, that, true or not, was so full of potential romance that we were strongly impressed with it.

Everyone knows that Martinique was the birthplace of the Empress Josephine. The Pagerie family still have estates there, and the old house in which she was born and the church with the baptismal records are shown to visitors. The daughters of the family of that generation all possessed great beauty, and a sister, younger than Josephine, excelled them all. After the marriage of the latter with Napoleon, a family council, in the hope of improving their reduced finances, determined to send the last daugher of the race to France to share in the brilliant fortune of her sister. She embarked for the port of Marseilles, and that was the last heard of the ship or of her beautiful freight. Years passed, and at last the news reached Josephine, while still at the side of Napoleon as Empress, of the strange and romantic history of her sister. The ship had entered the Mediterranean and was near her destination when she was captured by Barbary pirates. Passengers and crew were taken to an African port and exposed for sale as slaves, the beautiful Mdlle. de la Pagerie amongst the rest. The story of her marvellous beauty was so noised about that none of the dealers dare purchase her, for fear that the possession of a woman of such miraculous beauty would excite the jealousy of some more powerful Turk and cost the unfortunate owner his head. At last the fame of the beautiful captive reached the ears of the Sultan himself. A trusted agent was dispatched for her, and she was taken to Constantinople and disappeared in the Seraglio. From a slave girl she became Sultana, embraced the faith of the Prophet, and all the Sultans of Turkey since are descendants of the sister of Josephine, who was ruling in the land of her captivity, as near as a woman can rule in that polygamous land, while poor Josephine was enduring the humiliation and misery of a discarded wife.

This story is told in Martinique and firmly believed there. Mr. H. believed it, and relating it with all the embellishments and art of a good story-teller, held us entranced for nearly an hour on this night after Montserrat.

Ely Van de Warker.

NEWS ITEMS.

The Hoagland Laboratory.—The Trustees of the Hoagland Laboratory make the following announcement. Dr. George M. Sternberg, U. S. A., will continue as General Director of the Laboratory. George T. Kemp, Ph.D., Johns Hopkins University, will be Associate Director of the Departments of Physiology and Experimental Therapeutics. Dr. B. Meade Bolton has been appointed Director of the Department of Bacteriology, and will assume charge of that department in September.—*The Brooklyn Medical Journal*, August, 1889.

Typhus Bacilli in Water.—Several cases of typhoid have recently occurred in a town in the Province of Baden, Germany, and it came to light that three of the patients first affected procured their drinking water from the same well. The water was then examined, the strictest precautions being used to prevent infection from other sources. In three days the cultures were found to have developed on an average one hundred and forty thousand colonies to the cubic centimetre (about one-half cubic inch). Ten tests had been made, but only in one of these was there found a single colony of typhoid bacilli. —*Deutsche med. Wochenschrift*, July 4.

Vermont State Insane Asylum.—We learn from the *Boston Medical and Surgical Journal* of July 25th that Vermont is about to build a new State Insane Hospital at Waterbury. Five hundred acres of land have been purchased, of which thirty acres, in the vicinity of the Central Vermont R.R. Station, are to be used as a building site. The complete plans contemplate a three-story brick building, having a frontage of 900 feet. There will be a central administration building. The main building will consist of two wards, one for men and one for women, connected on each side by a corridor one story high. In each wing will be three two-story circular wards for the chronic insane. Each ward consists of a day room on the first floor, and a dormitory for 25 patients. There will be a general hospital ward, three stories high and 150 by 36 feet in size, with a capacity for 75 patients.

Italian Institutions for Rabies.—We learn from the *Lancet* of July 13th that Bologna, following the example of Milan, opened, on June 30th, an "Instituto Anti-rabbico," or institution for the treatment of rabies on the Pasteur method. The King, the Prime Minister, and the various civic and scientific bodies, as well as the townsfolk of Bologna, contributed the requisite funds. Every

considerable Italian city will soon, it is anticipated, be provided with an institution of the kind.

The Promotion of Illegitimacy in Vienna.—In connection with the obstetrical department of the hospital, and in the hope that the system would prevent induced abortions among the lower classes, the following plan was adopted some years ago: Any woman can enter the hospital, masked or not, as she desires; be known only by a number; live according to one of three grades—the cheapest costing about thirty cents a day; be attended in labor by skilful accoucheurs, and leave the hospital when she desires, with or without the child. If without the child, it is given a number, by which the mother can reclaim it even after years. When not reclaimed, the child, if a boy, is brought up as a soldier; if a girl, as a nurse. The only condition required of the mother is the payment of the small living fee (thirty cents a day), and enclosing her name and address of friends in an envelope to the secretary of the hospital, which is only opened in the event of her death while in the hospital. If all goes well, on her departure from the hospital it is returned to her unopened. This plan has, indeed, decreased the abortions and increased the population of Vienna, but it has also removed another check on free intercourse—the fear of becoming pregnant.—*The Medical Record*, June 15, 1889.

Rejected Contributions.—Medical editors are usually so glad to receive contributions that, whenever they feel obliged to reject a communication they do it in the gentlest manner possible, so as to discourage contributors as little as may be. It is, therefore, a matter of astonishment to read the reply which the editor of the *Medicinische Monatsschrift* makes to a contributor whose article does not please him. The unfortunate woman whose communication called forth the editorial strictures must indeed be thick-skinned if she was not hurt by the following, taken from the "Briefkasten" of the May number of the *Monatsschrift:* "Frau Emilie S., Buffalo, N. Y.: Your work on the 'Prevention of Yellow Fever and the Improvement of the Healthfulness of the Southern States,' we have returned to you as it is. Your ideas are not new and your way of writing not entirely correct. We do not know what is more to be regretted, the paper, the ink, the postage-stamps, or—a woman who knows no other way to improve her financial position than to discharge the cobwebs of her brain upon unsuspecting and harmless editors. Give up writing and take in hand the darning-needle and the coffee-pot; it is to be hoped you can work better with these useful objects than with the pen and the eucalyptus tree."—*Northwestern Lancet*, June 1, 1889.

A Submarine Expedition.—We learn from the *Lancet* that from Kiel will shortly sail an expedition to explore the submarine flora and fauna of the ocean, under the supervision of DR. HENSEN. The expedition, which is to last for several months, has been subsidized by the Emperor William to the amount of 80,000 marks. A special subject of investigation will be the effect of light on the oceanic fauna, and Dr. Henson, it is understood, will undertake a series of experiments with this object by means of a novel application of the electric light.

Pilsner Beer as a Diuretic.—DR. ADOLF GRUSS reports the following to the *Wiener klin. Wochenschr.*, June 14th. A female patient, aged seventy-four, suffering from valvular and mitral insufficiency, had for three months been treated with various diuretics without avail. The amount of urine excreted in twenty-four hours was only ten to seventeen fluidounces. The patient asked for Pilsner beer. Glad that she should evince a desire for nourishment, her wish was at once complied with. The first day she drank about ten fluidounces. To Dr. Gruss's surprise, on the same day, the excretion of urine increased to forty-four fluidounces. No other diuretic had been given for several days. It soon became manifest that as soon as she stopped taking the beer the excretion of urine again fell to eighteen or even ten fluidounces, but at once increased to forty-four fluidounces when the treatment was again resorted to.

Since then Dr. Gruss has prescribed Pilsner beer in many emphysematic patients suffering from hydrops, and its use has always been attended with marked success.

An Antidote for Phenic Acid.—The *Rev. de Thér. méd.-chir.* of June 15th recommends common soap as an efficient antidote in cases of phenic acid poisoning. The soap should be given as soon as possible after the poison has been taken, and continued until all toxic symptoms have disappeared.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM AUGUST 6 TO AUGUST 12, 1889.

By direction of the Acting Secretary of War, leave of absence for two months, on account of sickness, with permission to leave the Division of the Missouri, is granted ALFRED A. WOODHULL, *Major and Surgeon*.—Par. 5, *S. O. 178, A. G. O.*, August 3, 1889.

JANEWAY, JOHN H., *Major and Surgeon*, is hereby granted leave of absence for two months, with permission to apply for an extension of two months.—Par. 3, *S. O. 52, Headquarters Division of the Pacific*, July 29, 1889.

By direction of the Acting Secretary of War, WILLIAM B. BANISTER, *First Lieutenant and Assistant Surgeon*, is relieved from further duty at Fort Wingate, New Mexico, and will report in person to the commanding officer Fort Grant, Arizona, for duty at that station, relieving ARTHUR W. TAYLOR, *Captain and Assistant Surgeon*, who, upon being so relieved, will proceed to Fort Wingate, New Mexico, and report in person to the commanding officer thereof, for duty at that post.—Par. 4, *S. O. 178, A. G. O.*, August 3, 1889.

By direction of the Secretary of War, JOHN J. COCHRAN, *Captain and Assistant Surgeon*, now on duty at Fort Adams, Rhode Island, will report in person to the commanding general Department of the Platte, for temporary duty with troops en route to and at the summer camp at Fort Robinson, Nebraska. Upon completion of this duty, he will return to his proper station.—Par. 10, *S. O. 180, A. G. O.*, August 6, 1889.

By direction of the Secretary of War, the leave of absence granted WILLIAM C. GORGAS, *Captain and Assistant Surgeon*, in S. O. 84, July 3, 1889, Department of the Missouri, is extended two months.—Par. 2, *S. O. 182, A. G. O., Washington*, August 8, 1889.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL ARTICLES.

CLINICAL NOTES ON COCILLANA IN DISEASES OF THE LUNGS.

BY DAVID D. STEWART, M.D.,

LECTURER ON THE DISEASES OF THE SPINAL CORD, AND, LATELY, CHIEF OF THE MEDICAL CLINIC, IN THE JEFFERSON MEDICAL COLLEGE; PHYSICIAN TO ST. CHRISTOPHER'S HOSPITAL FOR CHILDREN.

SOMEWHAT more than a year ago my attention was directed to cocillana, a newly discovered drug said to possess therapeutic properties analogous to ipecacuanha and to be worthy of trial in pulmonary affections. Scepticism regarding the virtues of so-called "promising" new remedies, and disinclination to essay their trial when having at hand drugs the efficiency of which experience had left no doubt, caused me to use it at first only occasionally and a trifle perfunctorily, without attempting, in the hurry of practice, to keep records of results, until a number of favorable ones induced me to begin its systematic trial. I felt then more inclined to do this, understanding that the supply of ipecac root, which had diminished greatly in the past few years, was in danger of total exhaustion, owing to the continued large demand having resulted in the destruction of the plant in accessible localities in the limited area of South America to which its growth is restricted.[1] In view of this, it seemed desirable that a substitute for ipecac be found. Whether we have such in cocillana I am unprepared to assert, not having had opportunity for the thorough clinical trial necessary to permit authoritative statement. I have, however, no doubt that as regards the sphere of influence of the two drugs on the respiratory organs the effects are not unlike, and the results obtained from cocillana convince me that it possesses therapeutic properties which render it even superior to ipecac in certain diseases of the air passages in which the latter is often used.

Cocillana is the bark of a tree—a species of Guarea, of the family Meliaceæ. Like its near relative, the Goanese Ipecac or Naregamia alata, of India, it is used at the place of growth as an emetic and purgative (very rarely the latter), and is poisonous as an irritant-narcotic in over-doses. It contains apparently an alkaloid. It acts locally upon the mucous membrane either when directly applied or when absorbed; in the latter case it is quickly excreted through the mucous membrane, the upper portions of which are successively more active in the elimination. It is excreted very slightly through the skin.

Specimens from Eastern Bolivia were brought to this country by Dr. H. H Rusby and were described by Dr. N. L. Britton, of Columbia College, as being a new genus of plants in the family Anacardiaceæ, under the name Sycocarpus Rusbyi. A subsequent study of better material caused him to withdraw this opinion and class the plant as above stated, in *Bulletin of the Torrey Botanical Club*, July, 1889, p. 189.

Histories were taken of forty cases in which cocillana was prescribed. These comprise 10 of acute, 1 of subacute, and 19 of chronic bronchitis; 5 of broncho-pneumonia, and 5 of phthisis. Nineteen of the forty failed to report after the first visit. These are not considered here, although I think it likely that some of the cases of bronchitis among them were benefited, if not cured, as sufficient of the drug was always given to last at least twelve days, and its effects in full doses seem usually to be exerted promptly. Of the 21 remaining, 5 were cases of acute and 11 of chronic bronchitis, 4 of broncho-pneumonia, and 1 of phthisis.

The shortest time that any of these were under treatment by cocillana was 6 days; the longest, 12 weeks; the average, 22 days. In many of the cases other drugs had been unsuccessfully tried when cocillana was begun; they were then discontinued and cocillana alone used, save in one or two instances in which a few doses of digitalis, chloral, or a laxative were given to meet a special indication.

The following are brief, selected histories from the twenty-one:

CASE IV. *Acute bronchitis.*—T. C., aged twenty-one; clerk. First seen July 19, 1888. Had had frequent and troublesome cough for about a week, induced by exposure. Cough was loose and expectoration easy. The lungs were full of large and small moist râles with a few scattered dry râles. There was vesiculo-bronchial breathing; no alteration in resonance. The breath was offensive and the bowels constipated. A purge was given the first night and concentrated tincture of cocillana was prescribed in half-teaspoonful doses, to be taken every three hours. He returned in four days stating cough was worse and that medicine nauseated him. Two days later he reported he was no better. Cocillana was discontinued.

CASE V. *Chronic bronchitis.*—H. M., aged fifty; carpenter. First seen July 30, 1888. Had had

[1] Notes on Ipecac and Cocillana. H. H. Rusby, M.D. Pharmaceutical Record.

winter cough for twenty years. Present cough had continued since the preceding winter. Expectoration was moderate in amount, mucous in character; no emaciation; no albumin or sugar in the urine; heart normal; no alteration in pulmonary resonance; râles in chest (their character omitted from the records). He was ordered a half-teaspoonful of concentrated tincture of cocillana every three hours. Reported in a week that cough occurred less often, expectoration had diminished in amount and was more easily raised. Ten days later he was no better; cough and expectoration were about the same. A week subsequently cocillana was discontinued, no decided improvement having resulted after the first few days.

CASE VII. *Chronic bronchitis.*—S. M., aged eleven; school-boy. Had had cough more or less constantly for five years when first seen on July 13, 1889. It was then very troublesome and moderately loose, with muco-purulent expectoration. He had night sweats and was emaciated. A physical examination showed dry and moist râles and harsh respiration without alteration in percussion resonance. It was directed that the chest be pustulated with a mixture of croton oil and sweet oil, and five grains of ammonium chloride in a half-drachm of compound licorice mixture were ordered to be taken every three hours. This was continued until August 1st, but very little improvement resulted. Fifteen minims of concentrated tincture of cocillana every three hours were then prescribed. On August 17th, when again seen, he was decidedly better. He felt stronger; night-sweats had disappeared; appetite had improved; cough was much less, and expectoration was more easily raised. On the 24th it was noted improvement had continued; râles had disappeared, though the breath sounds were still harsh. Sufficient cocillana was then given to last a month, in doses of fifteen minims four times daily. On September 24th, when last seen, all signs of bronchitis had disappeared.

CASE IX. *Chronic bronchitis.*—Mrs. M. T., aged twenty-one; housework. First seen August 14, 1888. Had had cough for two years. It was tight, paroxysmal, very troublesome, and much worse at night. There was constipation. A physical examination of the chest showed no dulness; diffused râles, mostly sibilant and sonorous; heart normal. Cascara was prescribed for the constipation and concentrated tincture of cocillana was ordered, in fifteen minim doses, every three hours. On August 14th it was noted there was improvement; cough was less paroxysmal and less frequent; expectoration was easier. From this on, cocillana was continued in the same dose. She was seen every week or so until November 20th, when the paroxysmal cough had disappeared and râles could no longer be heard. Cocillana was then discontinued and the compound syrup of the hypophosphites substituted. She reported the following March that there had been no return of cough.

CASE XVIII. *Chronic bronchitis.*—D. K., aged fifty; clerk. First seen February 1, 1889. He had had winter cough for several years. The present attack had existed since spring. Cough was frequent and somewhat loose. There were present chest pains; no fever; clearness on percussion; diffused, moist râles; normal heart. Ten grains of ammonium chloride in a drachm of compound licorice mixture were ordered to be taken every three hours, until February 7th, when, not having improved, a half-teaspoonful of concentrated tincture of cocillana, at the same interval, was substituted for this combination. On the 13th he was decidedly better; stated last medicine had "done miracles." The expectoration had lessened in amount within two days, was more easily raised, and cough occurred less frequently. A few scattered moist râles could still be heard. On the 16th these had disappeared and cough was only present infrequently. On the 23d he reported that cough had entirely ceased. Cocillana was then discontinued.

CASE XXI. *Chronic bronchitis.*—X., aged thirty-four, physician,[1] had had cough with muco-purulent expectoration for two and one-half months, when he began treatment with cocillana in April last. Had been in the hands of a brother practitioner, who had prescribed various remedies without benefit resulting. Cough had become so troublesome at night that it prevented himself and others from sleeping. Night-sweats and complete anorexia were present. The bronchitis seemed at its worst when cocillana was begun. Ten minims of the fluid extract were taken three times a day. The cough ameliorated much at the end of the first day, and a comfortable night was passed. During the second day he was caught in a heavy shower and thoroughly drenched, and remained in this condition an hour. As a result, a severe spell of coughing occurred on rising the following day. Cocillana was continued through that day, and in the evening cough had quite ceased and the lungs seemed as comfortable as they had ever been. By the sixth day of treatment, cough had entirely disappeared A noticeable gain in strength was appreciable, no doubt due to the improvement in his general condition. Night-sweats had ceased and increase in appetite had been immediate and great. The latter was thought to be the direct effect of cocillana, as it appeared shortly after taking the first dose and seemed affected by each succeeding one. Cocillana was discontinued at the end of a week, he feeling well and there being no recurrence of cough. After several weeks of immunity, cough gradually returned, though not sufficient to cause any degree of annoyance except during one or two days when a fresh cold was caught. Believes that a regular and persistent use of the drug would have effected a cure.

CASE I. *Acute broncho-pneumonitis.*—J. C., aged forty; hod-carrier. First seen July 13, 1888. Had caught a heavy cold three weeks before. Cough had been quite constant since. It was somewhat tight; expectoration slight. There were constipation, anorexia, daily chilly sensations, slight fever and sweats. He was able to be about, though bodily weak. Dulness was present in small areas through the left lung. Scattered large and small dry, with a few moist, râles could be heard in both

[1] From notes furnished by himself.

lungs. He was directed to rub the chest with a mixture of croton oil and sweet oil, and fifteen minims of concentrated tincture of cocillana were ordered to be taken every three hours. On the 16th, he reported he felt improved. The cough had loosened in one and one-half days after beginning treatment. Expectoration was less in amount and more easily liberated. Constipation was relieved. The dose of cocillana was increased to a half-teaspoonful. On the 25th, the date of his last visit, he reported he felt much stronger and that cough had disappeared. I did not see him at this visit nor thereafter. As no examination of his chest was then made by the assistant in charge, I am unable to state if the areas of slight consolidation had cleared.

Case XVI. *Chronic broncho-pneumonitis and plumbism.*—P. S., aged twenty-six; house-painter. First seen November 7, 1888. Cough had existed since the preceding summer. It was alternately tight and loose. Expectoration was scanty. When he first appeared for treatment cough was difficult and painful and there were rheumatoid pains in the chest and shoulder muscles and in the large joints. He had had occasional light attacks of lead colic. There were present cold feet, headache, palpitation of the heart on exertion, sweats, a blue line on the gums, no constipation. There was dulness posteriorly at the lower part of the right inter-scapular space. Dry râles were heard in both lungs. He was directed to pustulate the chest with diluted croton oil, and potassium iodide in a stimulating expectorant mixture was prescribed. Potassium or ammonium iodide, and, occasionally, ammonium carbonate, in an expectorant mixture, were afterward ordered and continued until November 24th. At that date he was much improved and discontinued treatment, not returning for inspection until January 15th. The dulness was then less than at first, but cough was very troublesome. A careful examination of his sputum for tubercle bacilli gave negative results. Concentrated tincture of cocillana was prescribed in half-teaspoonful doses, every three hours. He reported on January 23d that cough had disappeared in two days after beginning cocillana. The dulness posteriorly still persisted. Cocillana was continued. He has not been seen since.

Of the cases of acute bronchitis, Case IV. alone made more than two visits, so that a report on the use of cocillana in the remaining four is somewhat incomplete. It was noted that two (Cases X., XI.), at the date of the second visit, were improved; cough and expectoration had lessened. One of these stated that the expectoration, though less in quantity, was more easily raised. These cases were of average severity and had lasted two weeks. In both, the cough was somewhat tight. One of the remaining cases (Case XIV., seen in February) reported that he was not improved, several days after his supply of cocillana should have been exhausted. He admitted not taking it with regularity. His occupation, blacksmithing, had exposed him to much sudden changes in temperature. In this case there was present an acute pharyngitis, in addition to a pronounced bronchitis of two weeks' duration. In the fifth case, which when first seen had lasted a week, there was no change after ten days' treatment under doses of fifteen drops of the tincture of cocillana. This quantity was afterward increased to a half-teaspoonful. As stated, the case was not again seen.

A more satisfactory report can be made on the cases of chronic bronchitis. Most of them were under observation for a longer period than the acute cases. When these appeared for treatment the average duration of the symptoms was thirteen months. The shortest period was two and one-half months; the longest, five years. Five of these cases were cured; three were decidedly and two moderately benefited. One (Case V.) seemed to mend at first, but the improvement was not maintained, so that cocillana was stopped. All of the five that were noted to be benefited but not cured, were doing well at their last visit, and the indications seemed to be that a cure would result if they continued treatment. It may be that some of these were cured and did not afterward report the fact, but of this there is no certainty.[1] Too great a press of work at that time prevented me from following the cases as closely as I desired.

All of the four cases of broncho-pneumonitis were improved as regards cough and expectoration, and two of them quite markedly. Histories of the latter two have been already related. One of the others, a lad of seventeen, who had had a broncho-pneumonitis of two weeks' duration, was cured by the ammonium salts, but suffered a relapse. There was a small area of dulness at the left base posteriorly when he re-presented himself for treatment. Cough was troublesome and expectoration difficult. Cocillana (concentrated tincture), in doses of fifteen minims every two hours, at first caused nausea, which, after a short time, disappeared. Cocillana was persevered in, but on the twenty-first day of treatment dulness at the left base persisted, though cough was much less troublesome and expectoration far easier than before this drug was begun.

The only case of phthisis in which cocillana was prescribed alone that afterward reported progress was not benefited. There was consolidation of the anterior and posterior apices on the left. Cough had been incessant for three weeks. There were night-sweats, loin pains, emaciation, and atonic dyspepsia. At first there seemed to be slight improvement, but on the twentieth day of treatment cough and night sweats were as bad as before and the general condition had not ameliorated.

A conjoint analysis of the twenty-one cases shows that sixteen of them were improved while taking cocillana, and that five of the sixteen were cured; that these five were cases of chronic bronchitis, and

[1] A renewal was given to each of the five at their last visit.

that the symptoms which were most distinctly influenced were cough, expectoration, night-sweats, anorexia, and constipation.

In all of the sixteen in which cough was not removed it was lessened. Expectoration was diminished in amount in all of the sixteen in which it was not entirely checked, and in six of the sixteen in which expectoration was difficult before cocillana was begun it became much less so later under this drug. In at least seven the cough became looser as it diminished in severity and frequency. The lessening in cough and in the amount of expectoration usually occurred within the first week. Another of the twenty-one (Case V.), who reported early improvement in cough and diminution in amount of expectoration, which also was more easily raised, stated at a later visit that this amendment was not maintained, so that this case is not classed with the improved in the above analysis. Two of the twenty-one (Case IV. and that of phthisis) stated that cough was aggravated rather than improved by cocillana.

Night-sweats present in three of the sixteen, disappeared in two. Appetite was decidedly and early improved in three who complained of its loss when they first came under observation. In three of the twenty-one it was noted that the bowels were somewhat looser while cocillana was being taken, though no laxative had been administered. It was not supposed that this was due to any special action of the cocillana until my attention was very recently directed to it by Dr. Rusby, the discoverer of the drug, too late for inquiry to be instituted as to its frequency in others who had made no mention of it in specifying results of treatment. Two cases made complaint of nausea while taking the drug in moderately full doses at short intervals. In both, however, this effect was quite ephemeral, soon ceasing though the medicine was continued.

It results from the foregoing analysis that cocillana is serviceable in bronchial catarrh, especially the subacute and chronic forms, when accompanied by scanty or moderately profuse secretion, whether the cough be tight or loose. It seems to possess the power to render cough less frequent and difficult and the bronchial secretion less viscid and more easily expectorated while at the same time it diminishes it in amount.

Perhaps the best preparation of cocillana for administration is the fluid extract, because of the relative smallness of the dose: seven and one-half minims of it equal about half a fluid drachm of the concentrated tincture. The fluid extract is to be preferred to the tincture in cases of acute bronchitis, since the amount of alcohol contained in the latter is apt to aggravate the inflammatory condition. In cases of chronic bronchitis, broncho-pneumonitis, and the bronchitis intercurrent with phthisis, the tincture is not open to this objection. The dose of the concentrated tincture I employed in most of the cases is, I am told, somewhat too small: an average dose equalling about three-fourths to one fluid drachm.

2620 NORTH FIFTH STREET, PHILADELPHIA,
August 1, 1889.

THE CLIMATOLOGY OF HEMOPTYSIS IN CHRONIC LUNG DISEASE FROM AN ETIOLOGICAL AND THERAPEUTIC STANDPOINT.[1]

BY ROLAND G. CURTIN, M.D., PH.D.,
OF PHILADELPHIA.

IN glancing over the field we are confronted by so many and varied influences of climate at work both in causing and preventing hemoptysis that the subject will be best considered by taking up each factor separately and discussing it, as to its bearings on the symptom under consideration, and then tabulating the result.

If the chronic lung disease is removed by climate, this, a mere symptom, is necessarily ended. We must be careful in our study not to magnify hemoptysis, which is, as we have called it, a mere symptom, into the prominence of a distinct disease. The great practical point for us is to consider the subject in such a way that an insight may be gained as to the best prospect of relief afforded by climate for our patient who suffers from hemoptysis.

We have all felt the want of a definite knowledge for the decision of a climate proper for a patient suffering from hemoptysis. Hemorrhage resulting in the sudden death of a citizen, away from home and relatives, may cause reproaches to be showered, perhaps deservedly, upon the medical adviser who has recommended a change of climate. A definite knowledge of this subject may avert such a catastrophe.

In glancing over the field certain points are suggested to us. First, I will give a brief summary of the more important causes of bleeding from the lungs in chronic pulmonary disease. We are liable to hemorrhages from the lungs caused:

1. By capillary congestion of the bronchial mucous membrane.
2. By congestion of the parenchyma of the lung.
3. From erosion of bloodvessels from the ulcerative process.
4. Predisposition from alteration of the blood, as in hæmatophilia.
5. Atmospheric influences.
6. Nervous influences.

The hemorrhage may be bronchial, capillary, arterial, or venous.

I will briefly enumerate the principal factors under the head of *climate* as we shall study it. It includes all the influences exerted on the atmosphere by the

[1] Read before the American Climatological Association, June 25, 1889.

geography, meteorology, geology, botany, and astronomy, whereby the human body is affected. The principal climatic conditions affecting hemoptysis are included under the following heads: heat, moisture, altitude, asepsis, rarefaction of air, etc., which will be separately considered, and in detail.

I will first take up the subject of *rarefied air*. It is usually a pure air, having no germs or malaria. An elevation of 16,000 feet takes off one-half of the air-pressure at the sea-level (fifteen pounds to the square inch). Any fraction of the above height has its corresponding effect on the surface pressure. The following experience of those connected with the Oroya Railroad, in South America, is given in *Bell's Climatology*, page 82:

"This withdrawal of pressure often occasions the most severe symptoms of vertigo, headache, nausea, and vomiting, all more or less alarming, and attended with profound prostration. The whole are attended with increased respiration and rapid action of the heart. Dr. Ward says some are affected with fearful nausea and vomiting, comparing it to the worst form of sea-sickness. Others suffer from severe frontal headache, palpitation of the heart, etc. From the violence of the heart's action it really seems at times as if it would burst the walls of the chest. Occasionally severe hemorrhage occurs from all the avenues of the body. The respirations are increased from three to five times a minute. Dr. Ward says he has counted forty-three respirations and 148 pulse in a minute at an elevation of only 9000 feet, and that the pulse is *always* increased in frequency but not in volume. A person who at the sea-level has a pulse of 75 per minute, would find it increased about ten beats at an altitude of 10,000 feet, and would experience ten additional beats for each 1000 feet of added altitude. The rule is that no one passes for the first time an altitude of 16,000 feet whose pulse does not mount to from 130 to 150 beats in a minute."

When a person rises rapidly in a balloon to a great height, blood sometimes oozes from the mucous membrane, owing to the withdrawal of the usual atmospheric pressure, and the increased pressure in the bloodvessels from increased heart action. This is the so-called "balloonist's hemorrhage." To illustrate more fully the effect of being suddenly brought into rarefied air found at a great elevation, I quote from *Bell's Climatology*, page 80:

"A most singular illustration of its effects was given me by Dr. Heath, who is the surgeon employed on one of the Peruvian railroads now building from Packasmayo to the Andes. While making this trip over the road with him, he informed me that the visible effects of this existing cause were quite common in his experience. He mentioned an incident he witnessed far up on the line of this road. He experienced one day as he approached a party of workmen on the road a severe and sudden pain in his side, causing him to 'double up.' He, however, managed to walk on, and one of the workmen hailed him to stop and see several men who were ill, and had been taken that instant with severe pains, etc. What was still more wonderful in his statement of coincidences, but which has since been vouched for by the others, was that at the same moment he felt this pain he saw two birds which were flying overhead fall to the ground and were picked up dead. The ordinary effects of *rarefied air* are a paralysis of the cutaneous nerves, and redness of the skin from dilatation of the capillaries. This effect on man might, if exerted upon a bird, produce sufficient shock to cause death."

If the bloodvessels and tissues within the lungs are weakened by degenerative changes, or if the bloodvessels are weakened by the ulcerative process, trouble might ensue from the decreased air pressure *without*, especially as the increased action from the heart *within* would assist in producing a hemorrhage.

To show you that simple rarefaction of the air may produce hemorrhage in chronic lung disease, I will cite a case which bears upon this point. A patient with a history of chronic cough and dyspnœa for three years, upon examination of the chest, gave indication by the physical signs of consolidation and some softening. He had never had hemoptysis. At the Hospital of the University of Pennsylvania we had an apparatus for the purpose of treating patients with rarefied air. After breathing a few inspirations of rarefied air for the first time, an alarming hemorrhage took place, which continued for half an hour. No hemorrhage ever followed this.

Dr. Theodore Williams, in the *Lancet* of May 12, 1888, in his data of the analysis of 141 cases of phthisis treated at an altitude varying from 5000 to 9000 feet, concludes that the climate is useful in cases of hemorrhagic phthisis, and that hemoptysis is of rare occurrence at the mountain stations. In the discussion of the paper of Dr. Williams, it was stated that the effect of altitude was to lower arterial tension, and that this might explain the freedom from hemoptysis. When hemoptysis did occur, it was owing generally to too sudden arrival at great heights. The hemorrhage was then of the order known as "balloonist's." Under any circumstances it will be safer to elevate your patient slowly. Where the ascent is by the conveyance of rapid trains, you can direct him to stop at stations on the road, so as to prevent the danger occasioned by a sudden arrival at a great altitude.

If the effect of elevation is to cause a lowering of arterial tension, as stated by some authorities, this gradual elevation of the patient will allow this factor to come into play, thus saving him from the danger of balloonist's hemorrhage.

Rarefied air is almost always associated with a dry and pure condition.

Sea air or *tide-water air* is a condensed air, and opposed to a rarefied condition of air in its action on the human frame, for here we have the full pressure of fifteen pounds to the square inch. Associated with the pressure, there is at the seaside a condition which is very unfavorable to tubercular patients. Besides the increased air-pressure without, and the increased arterial tension within, we have a slowed heart. Sea air is almost always moist, and this, with the irritation of salt always in the air,

hastens the ulcerative process, and counterbalances the good effect of the denser air.

In syphilitic phthisis the denser air and the increased arterial pressure are, I believe, beneficial in a curative way, as shown in my paper read before this Society two years ago in Baltimore. Seaside air, like sea air, is more moist than inland air; even more so than that at mid-ocean; but it is more variable as to temperature than out at sea or an island at the same latitude. The blood pressure is less from the slowing of the heart's action, and the denser air gives support to the bloodvessels, and the weakened tissues and weakened bloodvessels. These two conditions increase the danger of hemorrhage.

Another favorable condition experienced by a patient first arriving at the seashore is a result of a calming influence generally exerted over the nervous system, by which the patient will sleep longer and better for several nights. This quiet condition would in itself tend to prevent a hemorrhage, but, again, the ulcerative process is also generally hastened, tending later on to more danger. The air of fresh-water lowlands is apt to be dangerous to a patient from the miasmatic influences which are often present as well as from the increased moisture.

Cold air. What is the effect of a low temperature upon the body? The tissues and bloodvessels contract, especially the capillaries, driving the blood from the periphery toward the centre, not, however, with sufficient force to cause a dangerous internal congestion. Cold tones up the tissues in contact with the air, bracing them for their work. It has a beneficial effect upon the appetite, and favors assimilation, strengthens the nervous system, imparting internal vigor, while the lungs are also able to resist the increased blood-pressure within the arteries, owing to the strengthening effect of the reparative action of lowered temperature.

Warm air. The effect of continued warm air is to cause a debilitated and relaxed condition of the tissues and bloodvessels, which would in itself rather tend to the exudation of blood from the diseased tissue of the lungs. The influence of the relaxed state of the system at large, would have a tendency to diminish the force of the heart, thereby slowing the circulation, and consequently decreasing the danger of hemorrhage.

Dry air desiccates the pulmonary tissues, hence less moisture not only favors the return to health of the tissues affected by chronic disease, thus preventing the flow of sanguineous fluid, but it has also the immediate effect of preventing the oozing of blood from the surface of the altered lung tissue. Dry air is usually aseptic and the messenger of health.

Moist air influences the tendency to hemoptysis by causing a moist condition of the tissues, macerating and liquefying them, and it thus unblocks the bloodvessels, dilutes the blood, and makes it more fluid, all of which may cause the walls of the vessels to weaken, as well as a tendency to the breaking-down process in the lungs, causing a greater danger of hemorrhage. Moist air is usually the bearer of effluvia and miasma, which are detrimental to the health of the patient.

The air of an elevated region is usually an *aseptic air.* It purifies the blood, thus bracing up the system, favoring the healing process. This air is an anti-bacillary atmosphere, hence the healing process is assisted by the destruction of germs in the diseased lungs. An atmosphere of this kind is usually cold and dry, and aids in the arrest of decomposition. These factors all assist in causing an improved condition of the diseased tissue, which is the most favorable solution of the patient's case.

Home sickness (nostalgia) is one of the compli cations which sometimes attend a change of residence. It has a very depressing effect upon the mind and body, which may prove to be disastrous in a case with a tendency to pulmonary hemorrhage. To show the effect of depressing emotion on a case of hemoptysis, I will cite three cases that came under my observation.

Nervous influence may sometimes affect hemorrhages independent of other causes.

To illustrate the influence of the nervous system in producing hemoptysis as well as other hemorrhages I will first cite the case of a woman having a small phthisical area at the right apex, as shown by bronchial breathing, impaired resonance, progressive emaciation, and a slight cough, who was one day shocked by seeing a wagon draw up in front of her house. Supposing that it contained the body of her husband, she was immediately seized with a profuse hemorrhage, and died in a few moments. The corpse which had occasioned her alarm had been by mistake drawn up to the wrong door. It proved to be the body of a man who resided in the next house. In the autopsy it was seen that the lungs were merely indurated, the breaking-down process had not commenced.

To illustrate further the influence of the mind upon hemorrhage, I will cite the following case:

A child about twelve years of age, a patient of Dr. Ogden's, was suffering from typhoid fever, with profuse hemorrhages from the lungs, stomach, fauces, nose, mouth, bladder, and bowels. The amount of blood lost was sufficient, if it continued, to kill the patient in a few hours. We gave an unfavorable prognosis to the mother of the child. She went with tears in her eyes into the room where the child was lying. The child in a whisper said: "Did the doctor say I was going to die? Don't cry, mother, and I will get well." The blood in a short time began to flow less freely, and in about eight hours it stopped entirely.

The grief of the mother was a shock to the nervous system of the child, which, in my judgment, saved its life.

Here we have in one case an illustration of hemoptysis being caused by emotion, while, in the other two, of its being stopped by the same cause.

A woman with chronic phthisis was seized in the morning with a profuse hemorrhage from the lungs. In the latter part of the afternoon she was taken upstairs to her room, and a fire was kindled in a stove in which her son had previously concealed a quantity of gunpowder. An explosion ensued, destroying the stove. The greatest solicitude after the explosion was for the patient. But it was found that the bleeding had been summarily arrested by the shock of the explosion.

Homesickness will nullify the effect of any climate.

There are certain influences at work when a change of residence is made that are not enumerated in the foregoing list, which I think belong to climate, and as they may work to the advantage or disadvantage of a patient with a condition inclining to hemoptysis, I think them worthy of detail.

An out-door life is generally a life of exercise. The pure air favors repair, by improving the general condition, and is often a strong factor in a change of residence. Vigor is imparted to the system in general.

An in-door life is usually a life of quietude in a vitiated atmosphere which leads to a further degeneration of the diseased tissue, and is a cause of weakness. A feebleness of the system at large is engendered by such a life.

Sunshine. A patient living in a crowded city, shaded between walls, and with, perhaps, many cloudy days, is subjected to depressing influences. On removing a person so situated to a region with much sunshine, and to an out-door life, he will be benefited and greatly exhilarated by such a change. With such a change he will, of course, have a drier and purer air, which must tend to have a beneficial influence on the local condition. The general improvement incident to a change of residence is due to all the foregoing factors. All tend to strengthen the weakened tissues, and favor a cure of the existing cause.

Atmospheric influences. Aside from the usual climatic influences before enumerated, certain conditions seem to favor hemoptysis. I have noticed both in my private and hospital practice, several cases of hemoptysis developing on the same day. In two hospitals I have had from two to five cases develop, on the same day, under my care—a number greater than during the whole of the rest of the year—and these attacks lasting, perhaps, two or three days. They occurred in winter, in mild weather, and with a moist atmosphere. No epidemic of pneumonia or influenza followed this atmospheric disposition to hemoptysis. Phthisical cases are generally the sufferers at these times. No disturbances in the temperature of the patient follow these attacks. I have known three years to pass without any such hemorrhagic epidemic, and have observed two in one year, about two months apart. I recall five epidemics of this kind. And now, if I have two or three cases in my private practice, I ask the resident physician of the hospital, upon arriving there, how many cases he has. The answer is, "I have one, two, or three cases." What is the cause of the foregoing tendency? It seems to be atmospherical, but the specific cause I cannot give. I merely call attention to this observation that others may arrive at a true solution.

Having considered the factors and climate that influence hemoptysis, I will tabulate them under two heads.

First, the preventative and curative, and second, the causative.

PREVENTATIVE AND CURATIVE ELEMENTS.

Rarefied air tends to prevent hemoptysis by arresting the ulcerative or other diseased processes, and also by lowering the arterial tension. This climatic condition probably greatly overbalances the unfavorable tendency of the increased heart action, and loss of support to the lungs from diminished air pressure.

Cold air contracts the tissues and bloodvessels, thus preventing a flow of blood when a tendency to hemoptysis exists. It is beneficial by its general invigorating effects to the system at large.

Dry air robs the diseased structure of its moisture, decreases the fluidity of the blood, and blocks up the bloodvessels, all favoring the arrest and prevention of bleeding.

Aseptic air. The purity of this variety of air favors repair and cure of the lung disease, and kills or dwarfs the action of the disease germ.

Out-door life, when not associated with too much exposure, exertion, or fatigue, is beneficial.

Sunshine is beneficial, inasmuch as it improves the general nutrition.

CAUSATIVE ELEMENTS.

Sea-level air, by its greater density, diminishes the tendency to hemoptysis, but the increased arterial tension, and the moisture which are usually present in such a locality more than counterbalance the beneficial effect of the support given by the air pressure.

Salt air has a bad effect on tubercular lung disease by hastening the breaking-down process. The effect is probably good in syphilitic lung troubles, and sometimes in simple chronic inflammatory lung affections (not tuberculous).

Moist air has a very deleterious effect, by hasten-

ing the ulcerative process, as well as by liquefying the blood and secretions, and macerating the diseased surface in the lungs, thus rendering the tendency to the oozing and flowing of blood more liable.

Warm air relaxes the tissues and bloodvessels and enervates and relaxes the system at large.

From the foregoing arguments we should conclude that each case should be carefully studied, in all its phases, before deciding upon a change of residence. On a high mountain (say from 5000 to 10,000 feet), a residence far removed from the seacoast, is best for a patient with a tendency to hemoptysis. At a location of this kind one would probably have not only a rarefied, but also a cold, dry, aseptic air, factors which would be most beneficial. Care should be taken that the elevation of the patient should be gradual and not too rapid, otherwise the early effects of a sudden elevation might be followed by unpleasant results. A case of syphilitic phthisis will probably be benefited by sea air, while a tubercular patient would in all probability be injured by such a residence.

FACTS AND SUPERSTITIONS CONCERNING PREGNANCY AND PARTURITION, AT SWATOW, CHINA.

BY A. M. FIELDE, M.D.

NEARLY all the Chinese women maintain a sitting posture during labor and delivery. A few are unable thus to bring forth the child, and these are called "recliners."

The umbilical cord is never divided until after the emergence of the placenta, because it is supposed that this would cause the contents of the womb to rise and remain among the internal organs, causing speedy death. After the appearance of the placenta, the cord is tied by a thread, about one inch from the umbilicus; a loop is made by bringing the distal portion toward the body; a second knot is tied securely upon the first over the doubled cord, "to prevent the entrance of wind," and the cord is then cut near the second knot. The portion of the cord left with the placenta is not tied.

If there is much delay in the expulsion of the secundines, various methods are pursued in assisting the patient. The mother-in-law or midwife goes behind the house in which the patient lies, raps smartly with a carrying-pole on the wall, and shouts, "Is it out yet?" An assistant responds from inside the house, "It is out." This performance is repeated, with short intervals, until the desired result is effected.

Another method of hastening the expulsion of the afterbirth is to have the patient lean over a horizontal bar, supporting herself partially upon her hands. This sometimes starts the adherent placenta, but is discomforting to the attached infant.

Some midwives insert the hand and remove the placenta, but mothers greatly fear this operation. It is asserted that one woman had her liver pulled out by the attending midwife, and consequently died. Native male physicians are under no circumstances called in cases of childbirth.

A girl that is born face downward, or one that is guilty of micturition or defecation immediately after birth, is straightway smothered, because of a superstition that such a child will be injurious to its parents.

A pregnant woman is advised not to handle edged tools. If she does so, her offspring is likely to lack a finger or a toe, or to have a harelip or a split ear.

Two pregnant women will not sit together upon the same bench. As each woman hopes that her child is a male, and as it is thought that there may be an occult exchange of sexes between embryos that are brought into vicinage, it is considered wise to avoid the risk of having the supposed masculine tenant of the womb superseded by a female.

If a child has been touched by a pregnant woman, and sickens soon afterward, its mother winds a skein of silk, made up of threads of five colors, around a potato, and roasts the potato in the ashes. If the silk is burned during the process of roasting, it indicates that the ailment was not caused by the touch of the pregnant woman. But if the silk is not burned, as sometimes happens, then the mother of the injured child throws the potato over her house, and it is believed to produce a miscarriage in the woman who has caused the disease, while the sick child recovers.

Many men have purses made by women approaching confinement, hoping that the woman's plethoric condition will be mystically reproduced in the money-bag!

SWATOW, CHINA, April, 1889.

TREATMENT OTHER THAN CLIMATIC OF HEMOPTYSIS IN CHRONIC PULMONARY DISEASE.[1]

BY JAMES B. WALKER, M.D., PH.D.,
OF PHILADELPHIA.

IN considering the treatment of a symptom of even so grave a seeming as hemoptysis, the prognostic significance thereof is of much import. Is the occurrence of hemoptysis a grave indication? This query at once opens for consideration the various pathological conditions resulting in hemorrhage, and the response to it must be correspondingly varied. I take it for granted that we are united in considering hemorrhage from the lungs at times absolutely harmless and even remedial; and at others so serious as to demand the utmost efforts of

[1] Read before the American Climatological Association, June 25, 1889.

the physician in its arrest; and even at times, though happily rarely, so excessive as to produce a fatal issue before aid can be summoned.

Hemoptysis, early in phthisis, is, in the vast majority of cases, slight, and, unless long continued, calls for no medicinal interference. Hygienic measures usually suffice. These consist in placing the patient in a cool room, with light and loose covering, only sufficient to avoid a feeling of chilliness. His head and shoulders should be slightly elevated, except where syncope is threatened. During and immediately after the hemorrhage, rest of body should be enforced, the completeness of this rest being commensurate with the gravity of the hemorrhage or the dangers of a recurrence. It may necessitate as nearly absolute immobility of the entire body as is possible to obtain; the interdiction of speech; the use of the bed-pan and urinal for the ejecta, and the spoon or feeding-cup for the ingesta; and the muscles of attendants for all needful changes of position.

All mental and emotional excitement is to be subdued. The most important of these is fear, and, considering the gravity encircling in the popular mind, even a slight loss of blood from the lungs, it is not surprising that this should be. This is usually quieted easily by a calm and reassuring deportment of the physician, and is, of course, intensely accentuated by the slightest evidence of alarm or even anxiety from him. The bleeding organ should be especially placed at rest, and, in addition to the avoidance of speech, unnecessary coughing should be checked, usually requiring opiates in all cases of irritative cough, or where there is more than the slight effort necessary to remove the exuding blood.

The diet should be bland and digestible, small in quantity and, of course, nutritious. It should be given cool or cold. Milk, or, where acids are frequently repeated in the medication, the whey thereof, cold meat, teas, and ice. Water should be given sparingly, except where the hemorrhage is excessive, when it may be required more abundantly. So long ago as 1792, Davidson reported in the *Medical Facts and Observations*, published in London, two cases of hemoptysis cured (?) by total abstinence from liquids. Stimulants are to be avoided.

Attention to the various emunctories is important, especially the bowels, and slight saline laxatives are beneficial in even the mildest cases.

In many cases nothing further will be needed. In the graver forms, or in even slight attacks of patients naturally weak or debilitated by disease, more or even most decided efforts may be demanded, in addition to the purely hygienic. As nature is usually equal to the emergency, aided, unaided, or even when slightly hindered, a vast number of specifics have been vaunted. And it is equally true that as at times she is powerless, more efficient aids have been searched for.

Measures which relieve the local engorgement deserve, perhaps, first consideration. Dry or moist heat or counter-irritants to the extremities; aconite or veratrum viride; free saline purgation; iced compresses or ice-bag, limited to the area overlying the bleeding point where discernible, and kept in place but a little while at a time but frequently repeated; heat to the spine; venesection—of, however, questionable utility in any case of hemoptysis now under discussion, viz., in chronic pulmonary disease; Dr. Müller's substitute for venesection, an elastic bandage around one extremity, allowing it to remain for six or eight minutes, and applying another to the other extremity before loosening the first, which latter must be done slowly, a method contraindicated where the pulse is weak and blood poor in quality; dry cupping in the interscapular or infra-clavicular regions; the popular remedy, a spoonful of salt, whose efficacy, according to Skoda, is due to the gastric or gastro-intestinal irritation induced, are some of the measures by which relief to the area of engorgement is attempted.

The induction of measures to occlude the bleeding orifice by aiding the occurrence of the clot, and by diminishing the orifice to be occluded, call for measures classed as hemostatic, most of which aid directly or indirectly both objects. The astringents are thought by most to be efficacious hemostatics, and are used by most practitioners either internally or topically in spray or vapor.

For internal use gallic acid or acetate of lead is employed. If gallic acid is chosen, it should be given in ten-grain doses every two, three, or four hours. If acetate of lead is used, it may be given in pill with opium extract, unless the latter is contraindicated, or, as the Drs. Williams recommend, in five-grain doses in a solution containing an excess of acetic acid every two, three, or four hours, with a magnesium sulphate draught every morning to avoid the gastro-intestinal effects of the remedy. The mineral acids, and especially the sulphuric, are held in high esteem by many on account of the combined astringent, refrigerant, and roborant effects. Sulphuric acid may be used with other astringents or hemostatic factors and add not a little to their efficiency. A class of remedies similar in the results obtained, and, according to many close observers, more efficacious, is the essential oils, especially of turpentine and erigeron. These may be robbed of their one objectionable feature, their disagreeableness, by administration in doses of five or ten drops in capsule or closed French pearl or globule, or the closed soft capsule of Parke, Davis & Co.; the ordinary bivalve capsule is not admissible. Excreted in part by the pulmonary mucous mem-

brane, the terebinthinates are more certain to come in contact with the bleeding point or points, and, both rationally and by observation of many, they are more likely to arrest the hemorrhage, albeit their manner of doing so is not satisfactorily demonstrated, than are the astringents which depend for their local effect on the solution in the great volume of blood serum. Terebene may be substituted for the turpentine.

For topical application, alum is most vaunted; next to this a solution of iron perchloride and gallic acid; but, while these are usually chosen because they can be sprayed cold, I have seen the vapor of turpentine apparently promptly effective in a severe hemorrhage when these and other astringents had failed. It is stated that some of our North American Indians smoke Canada balsam mixed with their tobacco in cases of hemoptysis with apparent efficacy. Eucalyptus, matico, hamamelis, and a number of other astringent substances are used and, no doubt, useful; but it would seem desirable in most instances to depend on definite solutions of the active properties themselves than on more or less indefinite compounds, natural or artificial, containing them.

But of all the aids to nature in closing bleeding orifices, where aid is absolutely in demand, ergot must be given preference. This may be given by the mouth, but if prompt action is needed, should be administered hypodermatically, and repeated as often as the urgency of the case demands. If given by the mouth, it may be made more efficient by combining sulphuric acid, dilute or aromatic, repeated every four hours. Digitalis is frequently effective, and in weak hearts with lowered vascular tone it is strongly indicated. Its good effect is probably due chiefly to the contraction of the arterioles induced by it.

There are other plans of treatment which should, perhaps, be at least mentioned. The use of ipecac, so highly praised by Graves and Trousseau, administered to induce nausea, or even vomiting, is scarcely needed and is of doubtful advisability in the class of cases we are considering, especially when so many apparently less objectionable measures are at our disposal. Dr. Neale, in *The Medical Digest*, refers to the method in use by the Chinese and Malays in cases of hemoptysis. It consists in the administration of a half pint of the urine of a child. While this may be efficacious, it is not likely to be extensively adopted by civilized communities even as a household remedy.

If fever result, indicating local inflammation, active counter-irritation by blister or less violent agency; with quinine internally and the use of astringent or terebinthinate or antiseptic inhalations, should be resorted to. Rest should be enjoined in these cases until the fever subsides. But in the majority of cases enforced rest must be short-lived and cease with its necessity. After the hemorrhage has been securely arrested this measure should cease, and the disease which has occasioned it must be combated by improved nutrition, which will demand a certain and, of course, a varying amount of bodily activity and a more liberal dietary.

Preparations of larch bark have been used and may be substituted for turpentine, which they resemble in composition and effect. Hamamelis has proven effective, according to Brunton, in cases where ergot and digitalis have failed, while in others it has failed and they have succeeded. It may be given by inhalation or internally.

The treatment of hemoptysis during the attack is, however, not so important as during the intervals. Every case of hemoptysis, at whatever time occurring, from the incipiency to the stage of cavities, is of serious moment. As already stated, it is rarely of gravity in itself, but it is of gravity as indicating a pathological condition which makes a hemorrhage possible. As aneurisms are rare, save from direct violence to the artery, except where there exist defective vessels, so complete rupture and hemorrhage, as in hemoptysis, are perhaps always due to a diseased vessel. Notwithstanding the fact that the pulmonary capillaries have less extraneous support and are structurally most liable to rupture of any vessels in the entire vascular apparatus; yet, in the intensest engorgements to which as healthy vessels they are exposed in the first stage of acute croupous pneumonia. how rarely do we have a true hemorrhage Believing that hemorrhage in incipient phthisis is due, in the vast majority of cases, to vascular deterioration from bacillary invasion, we should take our suggestions in the treatment of such from this fact—if such it be—and place our patients under more favorable hygienic or dietetic conditions than they have previously enjoyed, else there is little hope for a permanent improvement or for the prevention of repetitions of the hemoptysis. To change of climate I may add change of occupation or habits, which will render the already diseased lung less vulnerable to bacillary invasion.

I recall for illustration a very marked and interesting case which occurred under my observation some years ago.

The patient was a man of about eighteen years who had about as extensive an inheritance of vulnerability as can be imagined. His uncles and aunts, of whom there were several, had all but one died of phthisis, and this one has since died of it after dragging along a semi-existence for some years. Both parents had died of phthisis. I cannot recall the history of the previous generation.

Frank was a tall, slender and frail boy, and was employed in the counting-house of one of the largest dry goods stores in Philadelphia. This counting-house, with glass sashes surrounding it, some of which were always closed, stood back in the store

and was lighted with several gas-jets the whole day through. In this deoxygenated den he had spent his working days for some months, when one day, about fifteen years ago, in the spring of the year, without warning, he had a hemorrhage of the lungs. The right apex was slightly infiltrated, and under rest the hemorrhage ceased after a few days. Under directions he quit his occupation, went to light work in the vineyard of an uncle who lived on a hillside bordering on one of the lakes in central New York. Returned in the autumn greatly invigorated, without objective or subjective sign of pulmonary disease, and by living an out-door life has never had a recurrence.

This is but one instance of many in the experience of, perhaps, all of us, where vulnerability has been changed to invulnerability by improvement of the environment.

To summarize the treatment I would say: Hygienic measures are adequate for the arrest of most cases of hemoptysis occurring early in chronic pulmonary disease. They constitute much the most important part in the treatment of even grave cases. In ordinary cases, in addition thereto, sufficient doses of an opiate to quiet unnecessary cough will be all that is required.

For the severer attacks, or where their repetition gives even a slight hemorrhage a gravity it would not otherwise possess, we should administer either the peculiar hemostatics, turpentine, erigeron, tincture laricis, or others of this class; or astringents, preferably gallic acid or acetate of lead, and these preferably by the stomach.

If topical applications are resorted to, they should be such as admit of perfect solution in the atomized fluids, as alum; or in the air inhaled, as turpentine, and forced efforts at inspiration with the idea of carrying into the lungs a large quantity of medicated air to mingle with the complemental and residual volumes are to be guarded against, lest the very effort to increase their efficiency shall increase the hemorrhage.

Where the hemorrhage is serious from its excess or persistence, ergot should be freely administered, by the stomach, if possible; hypodermatically if rapidity of action is imperative.

But in most, if not in all cases, hemoptysis should be considered due to bacillary invasion, and efforts to lessen the vulnerability of the patient should be resorted to and followed persistently.

MEDICAL PROGRESS.

The Treatment of Hip Disease.—Mr. Howard Marsh presents (*British Med. Journal*, August 3, 1889) the following conclusions in regard to hip disease when it is treated by continued rest, and without operative interference except the opening of abscesses as soon as discovered.

1. In the first place, the anticipation which would naturally be entertained that suppuration adds largely to the immediate danger of the case, and is injurious to the ultimate condition of the limb, is confirmed. In the stage at which cases are brought to the hospital suppuration is either already present, or it occurs after admission in about half of the total number of patients. In the previous report the proportion of suppurating cases was much higher (69 per cent.), and this decrease is a source of marked improvement in the general result.

In order to prevent suppuration it is of the highest importance that the disease should be recognized early, and be treated while it is still incipient. The more perfectly these conditions are fulfilled, the more limited will the proportion of suppurating cases become; and it is in this direction that the greatest improvement in the treatment and results of hip disease will, in the future, be attained. His own estimate, from what he has seen in the hospital and elsewhere, is that the formation of abscess may be averted by early treatment in at least 80 per cent. of the total number of cases.

2. In suppurating cases which recover, about 65 per cent. are good, and 35 per cent. moderate, cures. The average shortening is one inch; 50 per cent. are movable and 50 fixed; 65 per cent. walk well and 35 indifferently.

3. In cases without suppuration which get well 77 per cent. are good and 23 per cent. moderate recoveries; the average shortening amounts to two-thirds of an inch; 50 per cent are freely movable; 25 per cent. have slight movement, and 25 per cent. are fixed; 80 per cent. walk well and 20 per cent. indifferently.

4. The mortality due to the disease, as far as it can be ascertained in the cases he has reviewed, amounts to about 6 per cent., or if a wide margin be allowed for cases that may have ended fatally since they were lost sight of, although, when they were last seen, they were doing well, it may be safely said to be well under 10 per cent., while the mortality from general tubercular infection arising from the joint disease as a primary centre is well under 5 per cent.

A question that may naturally present itself is whether these figures are representative, or whether they are exceptional, and such as would not be confirmed were a larger number of instances taken into account.

He believes, from all he knows of the subject, that they may be accepted as typical; and he adds his conviction that the next group of a similar or larger number of cases that is published will show, not only as good, but still better results.

Now if we place the results of excision, so far as they have been recorded, side by side with the results of continued rest, he thinks there can be no doubt as to the conclusion at which we must arrive. Mr. Barker, last year, dwelt emphatically on the necessity of reducing the mortality attending tubercular joint disease; but the figures he quotes have reference to the mortality that follows excision. Thus, he gives Sach's table of 144 excisions of the knee, with 25 deaths (of which 13 were due to tuberculosis); Mr. Croft's 45 excisions of the hip with 18 deaths, 6 caused by tuberculosis; and Grosch's analysis of 120 excisions of the knee, with a mortality of 36.7 per cent., more than half of which depended on tuberculosis. The mortality here is undoubtedly so high that Mr. Barker's desire to reduce it is both natural and

praiseworthy. In Mr. Wright's cases, again, the mortality cannot be estimated at less than 20 per cent. On the other hand, in cases of suppuration treated without operation the mortality, he is confident, is not more than half this amount—that is, not more than 10 per cent. His strong impression is that it is materially less than this.

As to the ultimate condition of the limb, our information respecting the results of excision is limited. But, if we take Mr. Wright's table, we find that in less than 20 per cent. of his cases had the wound healed, while in 37 suppurating cases, treated without operation, and taken without selection, there were only 4 in which sinuses were still discharging; and in 65 per cent. the patients walked well and firmly, and without material lameness, on the limb. As to shortening, the average amount in 30 of Mr. Wright's cases was 1½ inch; in 35 cases treated without operation the average amount was 1 inch.

The treatment recommended is that of prolonged rest in the horizontal position combined with weight extension of the affected limb. This method, although of course it involves some important details, is, in principle, so simple and so well known that it is needless to describe it; but the method of dealing with suppuration claims more particular notice. All abscesses have been opened as soon as they were detected. An incision from an inch to an inch and a half in length is made, matter is evacuated by gentle pressure, and a small drainage tube, just long enough to enter the cavity, is used for two or three days. The dressing has consisted of carbolic gauze, next the wound, and this has been covered superficially with alembroth wool. The dressing is changed according to the case. In many instances the wound closes in a fortnight or three weeks, sometimes even sooner; in others it becomes a sinus, which discharges for a month or six weeks, and then heals; in others, again, suppuration remains free for several weeks, or even longer, and further openings have to be made; but at length, in a large majority of cases, the wound heals, and no further suppuration, except in a very few instances, takes place.

Sialagogue Mixture.—The following, which should be used as gargle, is claimed by DR. STICKER, in *Revue de Thér. méd.-Chir.*, June 1, 1889, to be a most efficacious sialagogue:

Rose water (distilled) . . .	f℥jx.
Tincture of capsicum } . . .	f℥jv.
Tincture of ginger }	
Powdered camphor	grs. xxxj.—M.

Treatment of Irido-cyclitis.—DR. SCÖLER, in addressing the Berlin Medical Society on the subject of irido-cyclitis, cited several cases in which he had obtained rapid cure by injections of a solution (one to two) of salicylate of soda into the vitreous humor of the eye. The amount injected was only one division of a Pravaz syringe. The result was most gratifying in every case. The hypopyon quickly disappeared in every case. In one case slight pain followed the injection; this, however, was only temporary. Injections of a two per cent. solution of carbolic acid were also tried in similar cases, but gave negative results.—*Deutsche med. Woch.*, June 20, 1889.

Tincture of Iodine a Cure for Warts.—DR. IMOSSI, of Gibraltar, has, according to the *Lyon Médical* of July 21st, been treating warts with internal doses of tincture of iodine. He has tested the efficacy of the treatment in ten cases, all of which resulted favorably. The dose given was ten drops of the tincture in half a glass of water, twice a day. Iodine thus used will cause a slight emaciation of the patient, which loss, however, will be regained as soon as the treatment is discontinued.

Amyloid Degeneration of the Pancreas.—At a recent meeting of the Kazan Medical Society, Dr. A. I. Podbelsky read an interesting paper (*Dnevnik Kazanskaho Obshtchestva Vratchei*, June and July, 1889, p. 2) on amyloid degeneration of the pancreas, in which he drew attention to the fact that the morbid lesion is by no means uncommon. Having lately made 122 consecutive necropsies (in 71 chronic and 51 acute affections), he found degeneration of the gland in 12 (9 83 per cent.). Among the cases were six men and six women, aged mostly from forty to fifty. Most frequently it accompanied tuberculosis (in 40 per cent. of all cases of the disease), and somewhat less so syphilis. Waxy degeneration of other organs was found in 25 out of the 122 cases. Macroscopically the gland was always more or less anæmic. In cases where the amyloid degeneration was well advanced, or where it was complicated with cirrhosis, the consistency of the gland was distinctly increased, while in the presence of but relatively slight waxy changes, combined with intense fatty degeneration, the organ was rather soft. Its weight was invariably found to be augmented in comparison with the standard. The same held good in regard to the dimensions of the viscus, except in two cases complicated with cirrhosis and atrophy. Under the microscope the degeneration was found to affect the walls of the arteries and periacinar capillaries, the membrana propria and fibres of the interlobular connective tissue. Fatty degeneration of the secretory cells and Renaut's *points folliculaires* was always present. Dr. Podbelsky believes that the disease may be diagnosed with probability during life, provided any new growths of the organ or obstruction of its duct can be excluded, from a chemical analysis of the patient's feces with regard to fats and starchy matters.—*British Med. Journal*, August 3, 1889.

Physical and Mental Changes after Removal of Ovaries or Uterus.—DR. GLÄVECKE, of Kiel, lately published a paper in the *Archiv f. Gynäkol.* on this subject. According to this author, the changes usually met with were those observed at the menopause. Menstruation permanently ceased immediately or shortly after the operation of removal in eighty-eight per cent. of the cases. In the remainder it was less frequent and more scanty. Practically no vicarious menstruation was observed. Menstrual molimina were observed in thirty per cent. In the time between the periods the familiar characteristic disturbances were observed—hot flushes, perspiration, and faintness. He looks upon them as disturbances of the vasomotor system, in consequence of the cessation of the ovarian function, an observation, by-the-by, that does not throw much light on the subject. He does not remark the very long continuance of this most uncomfortable condition in many of the cases—four and five years. In four cases out of a total of forty-three, palpitation and

headache came on, in one nausea, coming on several times a day, in another vomiting, in one diarrhœa, in one acne of the face lasting over a year, and in two increasing weakness of intellect. Atrophy of the internal genitals was a consequence of the operation. In twenty-three cases in which the operation was performed for myoma uteri, distinct shrinking took place in the tumors in ninety per cent. In forty-two per cent. of the cases a distinct increase in weight, due to deposit of fat, was observed. Sexual desire was unchanged after removal of ovaries in only a few women. Both desire and pleasure were much diminished, but not in the same proportion in all cases. As regarded the psychical condition, almost always a depressed, low-spirited condition was remarked. Many women became melancholic, others showed a changeable and petulant disposition. Actual psychoses developed in three cases; two recovered in the course of a year, the third was incurable.

The changes were different when the uterus was extirpated. Menstruation ceased, and no vicarious menstruation followed. Out of thirteen cases of total extirpation of the uterus strong molimina were observed in nine. If the ovaries were not removed atrophy of the external genitals did not take place. But little increase of weight took place after extirpation of the uterus. Sexual matters were almost unchanged, a slight diminution of sexual pleasure was acknowledged in a few cases. Psychically no change was observed in one-half of the cases; in more than a third a melancholy so great as to constitute a psychosis was observed. On the whole, the bodily and mental changes after castration were much greater than after extirpation of the uterus.—*Medical Press*, July 24, 1889.

Perspiring Feet.—In recent numbers of The News we have quoted several applications for fetid perspiration of the feet, last among which was a five per cent. solution of chromic acid, used in the German Army, and which has since proved successful in ninety-two per cent. of the cases upon which it was tried. The *Gazette des Hôpit.* of July 23d gives two additional formulæ, which are claimed to be most efficacious in overcoming this stubborn affection. Dr. Bardet gives one formula, which is as follows:

℞.—French chalk . . . . 40 parts.
Subnitrate of bismuth . . 45 "
Permanganate of potash . . 13 "
Salicylate of soda . . . 2 " —M.

This powder should be dusted daily into the stockings. The feet should be washed every morning and evening, and after washing, rubbed with alcohol.

The second method of treatment, which is recommended by Dr. Unna, is as follows:

℞.—Ichthyol . . . . . 5 parts.
Turpentine . . . . . 5 "
Zinc ointment . . . . 10 " —M.

This ointment should be applied after the feet have been bathed in water to which a little vinegar, mustard, or spirits of camphor has been added. During the day they may be dusted with the following:

℞.—Powdered mustard . . . 1 part.
French chalk . . . 30 parts.—M.

Two Cases of Antifebrin Poisoning.—The first case, reported in the *Münch. med. Wochenschrift*, No. 19, 1889, was that of a man, aged thirty-four, who fancied he had symptoms of fever, and procured from a druggist six antifebrin powders, of 15½ grains each. Returning home he took one powder every hour until five had been taken, beginning at 8.30 P.M., the total amount being seventy-seven grains. At four o'clock in the morning the patient was seized with violent diarrhœa. At about noon his appearance was as follows: Conjunctiva, lips and mucous membrane of mouth were blue; pulse small, but of normal frequence; heart normal. The urine gave aniline reaction. Extreme weakness, dizziness and chills; temperature 99° F.; evening, 101° F. Temperature on the following day, morning 95° F.; evening, 100° F. The diarrhœa persisted for several days, the stools being quite watery and of a grayish-black color. The patient suffered from loss of appetite, and recovered but slowly. In ten days he was able to be about again.

The second, which was reported in the *Wiener med. Presse*, No. 16, 1889, has the following history: The patient was a girl, who, to relieve an attack of hemicrania, had taken sixty-two grains of antifebrin. Immediately after taking the dose she experienced nausea, eructations, and later, pain in the region of the stomach and copious vomiting of a greenish watery fluid. These symptoms were followed by cyanosis, at first only of the lips, later of the entire face, hands and feet, whilst the skin of the body was pale and very cold. Pulse weak, almost imperceptible, but frequent, 140 pulsations to the minute; respirations shallow and rapid; the patient almost entirely unconscious. Later, symptoms of cerebral irritation manifested themselves; enlargement of the pupils, muscular twitchings of the face, gritting of teeth, rigidity of the extremities, and delirium. The patient then sank into a deep coma, from which she awoke in three hours.

Eight hours after the poisoning her senses fully returned, pulse eighty-four, and fairly strong; respirations normal, temperature somewhat sub-normal. Patient complained of pain in the stomach, and dizziness. Cyanosis disappeared in twenty-four hours. In two days the patient was able to leave her bed.

Treatment of Pruritical Affections with Menthol.—The analgesic properties of menthol render it valuable in diminishing the pain in pruritic affections, notably of senile pruritis, the pruritis of eczema, of itch, and also of urticaria.

For this purpose the drug may be either prescribed as a tincture, a liniment, or a salve.

I. Tincture or spirits of menthol:

℞.—Menthol . . . . . 1 to 3 parts.
Alcohol (at 104° F.) . . 50 to 60 " —M.

Sig.—For external application to the affected parts.

II. Menthol liniment:

℞.—Menthol . . . . . 3 parts.
Olive oil . . . . . 30 "
Lanolin . . . . . 30 " —M.

The action of this preparation is most efficient.

III. Menthol salve:

℞.—Menthol . . . . . grs. xxxix.
Balsam of Peru . . . f ʒjss.
Lanolin . . . . . ʒjv.—M.

In some severe cases the portion of menthol may be increased with benefit.—*Gazette hebd. de Méd. et de Chirur.*, June 21, 1889.

The Prognosis of Coryza in Young Children.—DR. J. SIMON, of Paris, recently writing upon the prognosis of coryza and laryngitis in young children, divides his observations under two heads: First, the prognosis of the above disease in infants, and, second, the prognosis in children above two years of age.

Acute coryza in infants always offers a grave prognosis. The accummulation of mucus in the nasal cavities causes difficulty in breathing, insomnia, and also a certain amount of fever. The prognosis is still more unfavorable if the disease takes a chronic form. The affection may become very intense and accompanied with fever and gastric troubles. Finally, it may also give rise to other serious troubles, and extend to the larynx and bronchi.

When occurring in children over two years of age, acute coryza is not so grave an affection, but still should be actively dealt with in order to prevent its encroachment on the larynx and bronchi. But at this age alimentation is accomplished with ease. Nevertheless, the disease may take a chronic form and give rise to osteoperiostitis, ozæna, tonsillitis, and even nasal polypi.

If in infants coryza takes a clearly acute form, it is always accompanied by more or less fever. In syphilitic cases, however, fever is absent, and there is a continuous running at the nose and a discharge of mucus in which, at times, traces of blood may be detected.

The prognosis of diphtheritic coryza is similar to that of diphtheria. Trousseau is of the opinion that laryngeal diphtheria is more fatal than the nasal form; but Simon considers either equally serious.—*Revue gén. de Clin. et de Thér.*, June 20, 1889.

Antipyrin in Sciatica.—In a stubborn case of sciatica, after all the usual remedies had been tried without avail (salicylic acid, iodide of potash, bromide of potash, quinine, etc.), DR. J. COVARRUBLAS, of Lima, determined to experiment with antipyrin. He accordingly prescribed doses of eight grains, three times daily. The pain disappeared entirely in one day, and ten days later the patient was able to leave the hospital, cured.—*Revista Médica de Chile.*

Treatment of Coryza.—Another "cure" for coryza is added to the already large list. We quote it from the *Centralb. für die Gesamt. Therap.*, No. 7, 1889:

Hydrochlorate of cocaine . . .	1 part.
Phenic acid	1 "
Menthol	1 "
Eugenol	2 parts.
Lanolin	15 " —M.

Sig.—To be applied to the mucous membrane of the nose by means of a cotton pellet.

The Value of Sulphonal in Mental Diseases.—After having experimented extensively with sulphonal upon a large number of cases of mental and nervous diseases, DR. GARNIER, in the *Deutsche med. Wochenschrift* of June 20th, comes to the following conclusions:

1. Sulphonal is a most valuable hypnotic in mental diseases. Sleep could be induced in nearly every case by doses varying from two to five grains.

2. Sulphonal proved itself of value in all cases where paraldehyde, urethan, and chloral were used without success.

3. Its tastelessness and odorlessness render it extremely applicable in mental cases, and the fact that it produces no injurious effects upon the heart, digestion, or respiration is an additional point in its favor.

4. Out of 100 cases, vomiting was observed in 5.50 per cent., and slight diarrhœa in 17.7 per cent. Such symptoms contraindicate the use of sulphonal.

5. The above symptoms are sometimes accompanied by dizziness and a staggering gait, similar to that produced by alcoholic intoxication; such should also contraindicate the use of the drug, particularly if any symptoms of congestion exist.

6. A diuretic action was observed to follow the use of the drug in 17.7 per cent. of the cases.

7. Single large doses do not have a soothing effect during the day, but produce sleepiness, and this indicates the advisability of decreasing the dose.

8. When sulphonal was given only every other night, the intervening nights were also observed to be spent in comparative rest.

9. In healthy subjects not suffering from any mental or nervous disorder, sulphonal induced a long and natural sleep. The accompanying symptoms were not noteworthy.

10. In females the action of the drug is more rapid than in males. In no case was the hypnotic action absent when the drug was given in single large doses; when the dose was divided, the results were but moderately good.

Treatment of Confluent Variola.—The following treatment of confluent variola, quoted from the *Rev. gén. de Clin. et de Thér.* of July 4th, is recommended by DR. BAUDOIN, of Mouy, France.

1. Apply, three times a day, the following salve to the face, neck, limbs, and body:

℞.—Salicylic acid	10 parts.
Vaseline	225 " —M.

2. After each application of the ointment, dust the entire body with the following powder:

℞.—French chalk	125 parts.
Salicylic acid	5 " —M.

3. Give, daily, three capsules of sulphate of quinine containing four grains each.

4. Gargles of borates will be found valuable.

5. Milk diet should be enforced.

The Infectiousness of Herpes.—Not long ago there was what might be called an epidemic of herpes in Dr. Unna's Hospital for Diseases of the Skin in Hamburg. All the cases occurred within five weeks, and in all five patients were affected. The primary case was one of herpes zoster on the chest of a man, three others had herpes labialis soon after, a fourth herpes facialis, and the fifth a herpes on the abdomen. DR. TÖRÖK, in the *Centralblatt f. med. Wissenschaft.* of July 27th, considers that this outbreak points strongly toward the infectiousness of herpes.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to The Medical News will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

SATURDAY, AUGUST 24, 1889.

THE TREATMENT OF FRACTURE OF THE PATELLA.

The recent history of the development of professional opinion concerning the methods of treatment of fracture of the patella is an illustration of the corresponding development which has taken place and is still going on in the entire field of operative surgery under the stimulus and the influence of the antiseptic theory of the treatment of wounds. Before that theory was introduced we possessed the knowledge of and habitually practised various non-operative methods of treatment of fracture of the patella which involved no risk to the life of the patient and discharged him with what was, in the great majority of cases, a thoroughly serviceable limb, although the broken fragments remained more or less widely separated and the union between them was fibrous and not bony.

Then came the antiseptic method with its promise of far greater freedom from the accidents and complications of open wounds. As experience was gained, confidence in the theory increased, the not infrequent disappointments were attributed to avoidable errors of technique, and the step to the far-reaching generalization that any operation that was anatomically possible was also justifiable and free from risk if properly executed, was easily taken by the enthusiastic disciple. With this came open arthrotomy of the knee and wiring of the fragments of the broken patella, an attempt to substitute an absolute *restitutio ad integrum*, a bony union without separation of the fragments, for the fibrous union with more or less separation.

Finally came the period of disillusion, the period of reverses and of promises fulfilled only in part. Granting that inflammation and suppuration are due to faults of technique, we have learned that those faults are not always avoidable, even by those who are most experienced and skilful. And at the knee we have learned that important functional defects after wiring of the patella are as frequent and as great as they are after non-operative treatment, and that, in addition, this operation has been followed in a considerable proportion of cases by suppuration of the joint, anchylosis, amputation of the thigh, and even death. But while this proportion of failures is large enough to justify the condemnation that has been set upon the employment of the operation in fresh, uncomplicated cases, yet it is still small enough to justify resort to it under exceptional circumstances, and to this extent it has become a valuable addition to our resources. It is, however, still necessary, as was shown in the recent discussion in the Philadelphia Academy of Surgery, to point out the dangers of the method and to check the tendency to undue expansion and generalization created by individual successes.

Meanwhile, under the protection of antiseptics other less radical and thorough-going operative procedures have been devised and the treatment of Malgaigne's hooks, now upward of half a century old, has won new favor. It must be admitted that treatment by splints and bandages alone, by means that do not act directly upon the fragments, does furnish from time to time a deplorable result, and that, as a rule, the failure is not recognized until after it has become too late to remedy it; consequently, the need for a more certain and trustworthy method exists. The problem is to bring the fragments together and to keep them together until a sufficiently firm union shall have taken place to render further external methods of retention unnecessary. The intervening curtain of fibrous tissue torn from the anterior surface of one of the fragments, with which the name of Macewen is associated (although it was previously noted by others) and to which so much importance is attached by some, is a bugbear. Such a curtain does undoubtedly exist in many cases, but its area is very much smaller than that of the fractured surface and it is not a bar either to bony union or to fibrous union of sufficient

strength and inextensibility. It does not, therefore, require or justify radical methods for its removal. So, too, with the presence of blood within the joint; its amount is seldom large, there is but little reason to think that it diminishes the subsequent freedom of motion of the joint, and if it should seem to require removal this can be done with an aspirator.

The methods in which the fragments are directly operated upon may be considered in two groups: those in which an external apparatus controls the fragments by means of metal pins passed through punctures in the skin to take a firm hold upon the bone; and those in which the fragments are temporarily or permanently bound together by metal or silk subcutaneous sutures, or subcutaneously transfixed by metal pins. Of the first, Malgaigne's hooks are the type, and the other members of the group are, indeed, only modifications of them. They are too well known to need more than a mention. Of the subcutaneous methods sufficient experience has not yet been gained to permit a final judgment of their availability. One of them, which has been quite extensively used during the past year by some of the New York surgeons, and which promises well, consists in passing a stout silk ligature through the tendon of the quadriceps and the ligamentum patellæ close to the bone and twice across the front of the fragments, through four punctures in the skin at the upper and lower corners of the bone, or through two transverse incisions, and drawing it snug and tying it while the fragments are held together with the fingers or tenacula. This was referred to in the discussion above mentioned as Volkmann's method, but incorrectly, for Volkmann's method was to pass two silk ligatures transversely, one through the tendon, the other through the ligamentum, tie each in a loose loop over the skin, and then to draw the loops together (and thereby the fragments) by an external cord. The difference may not be deemed radical, but the chance of suppuration seems to be less in the completely subcutaneous method, and it gives opportunity for an earlier employment of massage.

A somewhat similar method, but one requiring a larger armamentarium and offering greater operative difficulties is that of Ceci, an Italian surgeon, who brings the fragments together with the fingers, drills them diagonally from one lower to the opposite upper corner, draws a silver wire through, passes it under the skin to the other lower corner, drills the bone again on the other diagonal, and draws the wire through it and then under the skin across to be twisted with its other end. Dr. T. G. Morton passed the drills along the two diagonals and held the fragments together by clamps placed on the projecting ends of the drills.

To summarize, then, we may say that the old method of immobilization of the joint upon a posterior splint with retention of coaptated fragments by bandages will furnish a large percentage of successful results, and is to be employed in default of special instruments, or of the opportunity to carry out operative methods with the necessary protection; but it requires that the fragments should be left uncovered for frequent examination in order that subsequent separation may be promptly detected and remedied.

Malgaigne's hooks, in any of their modified forms, accomplish their object with much certainty and freedom from risk, but occasionally troublesome suppuration occurs.

The various subcutaneous methods hold out a fair promise of both efficiency and freedom from risk, with the advantage that the patient needs close supervision for only a few days, or until the punctures in the skin shall have healed. He can then be dismissed with a plaster splint, to be worn for a month, with no anxiety lest the adjustment of the fragments should be disturbed.

The operation of opening the joint and wiring the fragments should be used only under exceptional circumstances.

POISONOUS TEXTILE FABRICS.

THE occurrence of eruptions in those wearing colored fabrics next the skin is not rare, but our knowledge of the substances most likely to produce such poisoning is not exact. Arsenic in various combinations frequently produces marked irritation. At a recent meeting of the Berlin Medical Society, WEYL (*Münchener med. Wochenschrift*, No. 23, 1889), in a paper upon this subject, considered dye-stuffs not so poisonous as the mordants by which they are applied to the fabric. Among the few carefully analyzed cases of such poisoning which he had collected, he found an epidemic of lead poisoning among workers in yarns at Lyons who used lead chromate in a yellow dye. Saddlers use thread similarly colored. In another instance, a tricot material was found to be colored yellow with saffranin; this dye was intensely poisonous to animals by subcutaneous injection, although harmless

when swallowed. Eosin produces an eruption when used as a dye, but is not poisonous. In a case of poisoning ascribed to material dyed with indigo, an excess of sulphuric acid was found the active agent. Indigo itself is innocuous.

In the discussion following, pityriasis rosacea was reported to have followed the wearing of tricot materials; chrysoidin, a yellow powder, was also observed to cause severe irritation among workmen who used it in dyeing. A certain allowance must be made in such cases for individual susceptibility, for as persons vary in the irritation produced by articles of diet, so they differ in susceptibility to irritants in clothing.

In prophylaxis the rule should be made that no colored article should be worn next the skin which has not first been boiled. This simple precaution is usually sufficient to prevent poisoning by poisonous fabrics.

We are in receipt of a formal announcement from Professors von Bergmann, Virchow, and Waldeyer, that according to the resolution passed at the Washington meeting, September 9, 1887, the Tenth International Medical Congress will be held in Berlin. The Congress will be opened on the fourth and closed on the ninth day of August, 1890. Detailed information as to the order of proceedings will be issued after the meeting of the delegates of the German medical faculties and medical societies at Heidelberg, on the 17th of September in the current year. Meanwhile they extend a cordial invitation to attend the Congress. An office has been established at Karlstrasse 19, Berlin.

The fourth session of the French Congress of Surgery will be held in Paris, from the 14th to the 20th of October of this year, Baron Larrey presiding.

The following subjects will be brought forward for discussion:

1. The immediate and remote results of practical operations for local tuberculosis.
2. The surgical treatment of peritonitis.
3. Treatment of aneurisms of the limbs.

The American Pediatric Society, which was organized at Washington last autumn, will hold its annual meeting at the Army Medical Museum building, Washington, D. C., on the 20th and 21st of September, under the presidency of Dr. Jacobi. The preliminary programme has just been issued, and includes papers by Blackader, of Montreal; Booker, Latimer, and Osler, of Baltimore; Jacobi, Dillon Brown, Caillé, Fruitnight, Huber, Koplik, Northrup, O'Dwyer, Seibert, Lewis Smith, and Vineberg, of New York; Earle, of Chicago; Jeffries, of Boston; Love, of St. Louis; Meigs, of Philadelphia, and Vaughan, of Ann Arbor.

We are informed that Dr. J. R. Taylor, of Phillipsburg, Pa., has been elected to the chair of Pathology and Practice of Medicine in the Medical College of South Carolina.

The U. S. Grant University has organized a medical school, with a complete faculty, at Chattanooga, and the winter course opens on October 7th.

An ancient treatise on anatomy has been unearthed at the Royal Library at Berlin. It was written in Latin in 1304, by Henry de Mondeville, professor of surgery at Paris and Montpelier, and body-surgeon to Philip le Bel. Surgeon de Mondeville was at one time on English soil as an army surgeon, and his death took place in 1318. The book has never been printed. It is valuable as throwing light upon a period, concerning whose medical history there is but little known.

The Baly Memorial of the Royal College of Physicians has been awarded to Dr. Heidenhain, of Dresden. It consists of a gold medal, and is issued every second year for some noteworthy accomplishment in physiology. Bernard, Darwin, Brown-Séquard, and Ferrier have been among those who have received the Baly medal.

Dr. Harvey E. Brown, Major and Surgeon, U. S. Army, died of consumption last Tuesday at Jackson Barracks, near New Orleans, and was buried at the National Cemetery at Chalmette on Thursday. He was a son of Col. Harvey Brown of the Fifth Artillery. Graduating at the University of New York, he entered the army as Surgeon in General Sickles's Excelsior Brigade (Seventeenth New York) in 1861 and rendered notable service. He saw considerable service during the yellow-fever epidemics in the South during the past twenty-five years. He was the author of a report on a "More Efficient System of Quarantine on the Southern and Gulf Coasts" (1872) and of a history of "The Medical Department of the United States Army from 1775 to 1873" (1873).

SOCIETY PROCEEDINGS.

PHILADELPHIA ACADEMY OF SURGERY.

Stated Meeting, June 3, 1889.

J. EWING MEARS, M.D., IN THE CHAIR.

(Concluded from page 191.)

DR. F. H. GROSS reported a case of

FRACTURE OF THE PATELLA TREATED BY MALGAIGNE'S HOOKS

in the German Hospital. About three months ago the patient fell and fractured the right patella. He was admitted to one of the hospitals in this city and treated by hard pads above and below the patella. After remaining in the institution four weeks he left and began walking about. At this time there was separation wide enough to receive his finger. After going about for a week he fell and severed the ligamentous union. He was then admitted to the German Hospital, and as soon as the swelling subsided a modified form of Malgaigne's hooks were applied. This was April 27th. The hooks were allowed to remain in position three weeks, and it is now three weeks since they were removed. The union is very close, but whether it is bony he could not say.

This is the second case in which he had used this instrument. He saw the first case some months after he left his care, and the union seemed to be bony. The result was very good.

Where the hooks are secured together by a screw, the screw is apt to become rusted, and in removing it a portion of the bone may be chipped off. He has modified the instrument by having the upper and lower pairs of the hooks slide together. On the upper surface of each is a projection, by means of which they can be secured together, first by thread and then by a strong rubber-cord. This tends to keep up a steady and continuous traction, so that anything between the fragments of the patella will be subjected to constant pressure or forced out. Each section of the instrument is furnished with a removable handle, by means of which it can be conveniently held and applied. In fixing the hooks he drives them well into the bone.

DR. THOMAS G. MORTON said that the usual method used in treating fractures of the patella by compressing all the tissues about the knee-joint interferes materially with the circulation, and undoubtedly tends to want of bone union, which is not the case when the fragments are held together by hooks, pins, or by suture. The Malgaigne hooks he had often used, and only in one instance was he obliged to remove them on account of irritation produced. He has also used a long steel pin for retaining fragments in position. Now, with perfect antiseptic precaution, the joint can be opened, the fragments approximated by suture with little danger and with fair prospect of bone union.

DR. J. M. BARTON said that Macewen states that where the patella is broken by muscular action the overlying tissues are stretched and ruptured and fall in between the fragments preventing bony union, and nothing less than opening the joint and removing these tissues will permit bony union. When the fracture is due to direct violence, of course, these tissues are not stretched and ruptured, and do not prevent bony union. When, however, the fracture is due to muscular violence and the fragments are not widely separated, it is possible that the overlying tissues are stretched but not ruptured, and bony union may perhaps be obtained without any operation. The existence of soft tissues between the fragments might be determined by the amount of crepitation obtained on rubbing them together. He had opened the joint and wired the fragments in two cases. In the first case the patella was broken into three pieces by muscular violence. It occurred while the patient, a heavy man, was jumping off a moving car; before he fell to the ground he felt the fracture. He stated that he felt two distinct snaps. Owing to the complicated manner in which the speaker was obliged to pass the wire he felt that he would not be able to remove it, so he cut the ends short and buried them in the patella. The man made a perfect recovery from the operation; there is bony union, but he has a very limited motion at the joint. In the second case the line of fracture was straight across and was also due to muscular action. This case was treated at the Jefferson Hospital about three months ago. He removed the wire six weeks after he inserted it. He also has good bony union and is already able to bend the leg nearly to a right angle. In neither case was there any danger to life. In both he was able to verify the statement of Macewen that there was a layer of tissue between the fragment. It lays over each rough broken surface and is closely adherent to it; it can be raised up, but when released it falls back into position. In the first case the layer over each surface of bone was at least one-eighth of an inch thick. He trimmed them carefully off with scissors after they were raised.

DR. CHARLES B. NANCREDE said that there is one point in regard to the anatomy of the knee-joint to which Hamilton has called particular attention, and which explains the stretching. The patella is attached to the tibia not only by the tendon of the rectus which, passing downward, forms the ligamentum patellæ, but also by the expanded tendons of the two vasti which are extended downward and attached to the epiphyseal line of the tibia. He states positively—and Dr. Nancrede thought that his observations confirm the statement—that if at the time of the injury there is an inch separation, due to a tearing of an inch of this fibrous hood of the quadriceps, there will be an inch of separation when the patient has used the limb for, say, a year. If there is two inches original separation there will be the same amount when the patient gets well, unless bony union is secured. There will be no separation unless the fibrous hood of the quadriceps tendon is torn, and the extent of the separation will be in proportion to the extent of this tearing.

He recently had an interesting case which was sent up from the dispensary, confirming these statements. The man stated that he had injured the patella about a week previously, since when he had pain in walking. There was a transverse fracture readily made out. There had been no tear of this fibrous hood, and there was no separation of the fragments. By rubbing the two fragments forcibly together in a lateral direction distinct bony crepitus was elicited, and the finger-nail could follow the transverse fissure across the whole extent of the bone. These peculiar points were readily detected by his interne and by one of his colleagues.

DR. WILLIAM G. PORTER desired to hear the experience of the Fellows in regard to the result in these cases

where there is considerable separation, and what amount of motion is recovered eventually. It had been his fortune to see one or two cases in which the result was unusually good, but, of course, we do not often have the opportunity of following these cases to their termination. Some years ago he had a case at the Dispensary of St. Mary's Hospital where the separation was sufficient to admit three fingers. The patient came with a leg ulcer, not to be treated for the knee trouble. He seemed to have as good motion in the one knee as in the other and he said that the limb was just as useful as the uninjured one. He had seen a similar case at the Philadelphia Hospital. He did not know whether or not this was an isolated experience.

Dr. J. Ewing Mears had been much interested in this subject during the past year, and had asked himself whether it would be well to change the nomenclature in these cases and speak of them as rupture of the tendon of the quadriceps extensor femoris with fracture of the patella. There may be a rupture below, or it may occur above, or it may take place through the patella. He thought in these cases we should regard the tendon rather than the bone. The fracture of the bone is incidental. In these cases where the injury is the result of muscular action, the tendon is the part to which attention should be devoted. If we suture the tendon and keep the limb quiet we shall secure as good union as by any plan the object of which is the consolidation of the bone. The rupture of the tendon is the important element. Where the fracture is the result of direct violence there is no separation because the tendon is not stretched or ruptured. Rupture of the tendon, with or without fracture of the small bone which it encloses, should be treated in the same manner as rupture of a tendon in any other part of the body—by careful suturing and prolonged rest until a firm union occurs. The occurrence of *complete* rupture of the tendon with fracture of the bone as the result of muscular action is very rare, if indeed it ever takes place, and the recurrence of separation of the fragments after treatment in many cases is due to the incomplete and imperfect adhesions which have formed between the foldings of the elongated and partially ruptured fibres of the tendon. As soon as the limb resumes its function these adhesions break, the tendon unfolds partially or completely, causing separation of the fragments of the bone which is part of the tendon.

The proper treatment would seem to be exposure of the tendon by an incision, retrenchment, and accurate apposition of the edges of sutures, by means of which the fragments of the patella will necessarily be brought into apposition and osseous union occur. In place of this operation, which is not entirely devoid of danger, the method of Volkmann may be employed, which consists in passing a silver wire or a strong silk ligature subcutaneously though the tendon of the extensor muscles, and the ligament of the patella by which procedure he has obtained excellent osseous union in a number of cases. In all cases prolonged quiet of the limb is most important, use being prohibited for at least a period of three months.

Dr. J. M. Barton: In reference to the question of Dr. Porter, I would say that the cases he had seen had been very unfortunate. He had certainly met with eight or ten cases in which the other patella was broken, and in at least three the same patella has been rebroken.

When the fracture is treated in the usual manner, without opening the joint or wiring the bones, we obtain tendinous union, all that Dr. Mears claims, and this tendinous junction stretches and occasionally breaks. The point which had been made in regard to the tendon is a good one. If we cut down to suture the tendon, we should not neglect to wire the bone. The risk would be as great, the joint is quite as much exposed in suturing the tendon as in wiring the bone. Suture of the tendon will not be sufficient, though it might be done at the same time.

One case had been under the care of a colleague; the patient broke his patella, and two years later broke the bone of the other side. About six months later he refractured the first patella. A short time later he broke not only the ligament of the same patella, but also ruptured the skin over it, making a compound dislocation of the joint. The fragments of bone were a long distance apart, and the remaining ligament was so trifling in amount that it would evidently be useless if sutured. It was decided on consultation to excise and make a stiff joint.

Dr. F. H. Gross said that there was a case in the marine department of the German Hospital under treatment for some medical trouble, who had had a separation of the ligament of the patella. This bone was some distance above the joint, and the condyles of the femur could be felt below it. He had, however, good use of the limb. It was clearly shown that its usefulness was dependent upon the accessory tendons from the vasti muscles. When he raised the limb these tendons came out very distinctly.

Dr. William Hunt did not wish to say anything against reasonable efforts to obtain the best possible results, but whilst listening to this discussion it was impossible for him to recall a single case in which any permanent serious disability had arisen from fracture of the patella. No matter how great was the separation, good functional result was secured, and the patients have been able to go about and attend to their business. With such an experience he could not justify what appeared to him to be rash operative measures in treating single fractures of the patella. He had recently read of three deaths from opening the knee-joint, washing out, and wiring. Again, he had watched cases thus treated by others. The results have been no better than those obtained by the old and safe methods. Have we, therefore, he asked, a moral right to risk life when there is no occasion for doing it?

Dr. Nancrede had seen one case in which there was a separation of several inches, with an admirable functional result. He recalled another case in which the patient fell and broke the ligamentous union between the two fragments of a broken patella. It would have been impossible to wire the fragments together without dividing the quadriceps tendon freely. He did the best that he could, but the result was very poor. Hamilton in his work on *Fractures of the Patella*, reporting one hundred and twenty-three cases, states that ligamentous union is as good as bony union even if this can be attained. This statement was made before the time when the fragments had been wired together sufficiently long to judge of the risks and advantages. He cites case after case in which there was great separation, but in which the functional result was good in support

of his view. The speaker had used the modified Malgaigne's hooks where there is any tendency to separation. In any case where he operates by incision and wiring he should suture the tendon as Dr. Mears suggests.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON ORTHOPÆDIC SURGERY.

A. B. JUDSON, M.D., CHAIRMAN.

Stated Meeting, March 15, 1889.

CICATRICIAL CONTRACTION OF FINGERS.

DR. A. M. PHELPS presented a patient on whom he had operated four weeks ago for restoration of motion to the fingers, which had been flexed in the palm by a cicatrix in the wrist of eight years' standing. He had freed each tendon from the cicatricial tissue and had secured healing by blood-clot, with the hope that new sheaths would be formed in the clot. The wound was dressed antiseptically, and the first dressing was changed at the end of three weeks. The prospect of recovery of motion was good.

DR. R. H. SAYRE said that Paget had long ago recognized the organization of blood-clot after subcutaneous tenotomy. The case presented by Dr. Phelps shows that advantage can be taken of it after open incision under antisepsis.

DR. N. M. SHAFFER presented a patient, a girl of twelve years, who had been affected for ten weeks with

HYSTERICAL EQUINO-VARUS

and rhythmical movement of the left foot. The talipes was reducible manually, but the motions were persistent. There was inability to walk, the result of the disability of the quadriceps extensor group. Before coming under Dr. Shaffer's observation plaster-of-Paris had been applied to the limb for several weeks, but without benefit.

DR. A. B. JUDSON thought that choreic elements were seen when the patient attempted to walk. He recalled a case of rhythmical myoclonus reported by Dr. Peckham in the *Archives of Medicine* in 1883, in which the patient had been subjected to a great variety of treatment, and finally recovered after the hypodermatic use of atropine.

DR. S. KETCH suggested treatment by hypnotism.

DR. R. H. SAYRE thought that the case illustrated the fact that abnormal muscular contraction can produce degrees of deformity as marked as those caused by bony distortion.

DR. L. W. HUBBARD thought the case allied to chorea, being the result of nerve irritation or exhaustion. He suggested absolute rest or recumbency for a long period with efforts to improve the nutrition.

DR. A. S. HUNTER had treated with success a case of hysterical hip by the administration of ignatia amara. The use of this drug in a number of cases of this kind had led him to value it highly when the disturbance was limited to groups of muscles only; but he thought it was of little value in the treatment of general choreic conditions.

DR. V. P. GIBNEY had had a favorable effect in a case of rotary spasm of the neck, from the fluid extract of gelsemium, given in five-minim doses, and pushed almost to toxic effects.

DR. H. W. BERG said that the contractions in the case shown could not be due to nerve lesion because it yielded so readily to manual replacement. Where there is irritation of motor nerves as in spastic paralysis, it is extremely difficult to reduce the limb to a proper position. He suggested the ordinary treatment of chorea with electricity to make an impression on the mind rather than on the nerves.

DR. PHELPS then read a paper on

THE MANAGEMENT OF HIP-JOINT DISEASE FROM AN ANATOMICAL BASIS.

In regard to the pathology of hip disease, Dr. Phelps believes that it is a local tubercular affection, due to accidental inoculation and not to a constitutional or strumous condition. Following Volkmann, Albert, and Konig, he believes that the inflammation, at first simple, becomes tubercular by inoculation, and then purulent. The irritation of the peripheral extremities of the nerves in or about the joint produces muscular spasm, which in turn distorts the joint by trauma, aided by the bacilli of tuberculosis.

In regard to treatment, he relies on mechanical treatment, believing that if we immobilize a joint and remove the intra-articular pressure, Nature will take care of the tuberculous material. His experiments on dogs had convinced him that immobilization of healthy joints does not produce ankylosis. Encouraging motion in an inflamed joint is a violation of the surgical law that an inflamed part requires rest. He believes that the muscular spasm, which is a most serious element of destruction, should be overcome by extension, and that while extension is necessary to secure immobilization, it is not sufficient by itself. He, therefore, resorts to a combination of extension and fixation; the extension always to be in a line corresponding to the axis of the neck of the femur.

Treatment as a rule should be begun in bed, extension being made in two directions, *i.e.*, toward the foot-board and laterally, the body and well leg being fixed to a long splint extending to the axilla. If the deformity does not yield to extension properly applied, the tissues at fault should be divided subcutaneously or by open incision. Abscesses are to be incised through their entire length, and thoroughly scooped out and washed, strict antiseptic precautions being observed.

Distention of the capsule should be relieved by aspiration or incision; then traction will not produce pain.

He exhibited a patient in a portable bed, which is an ingenious substitute for the wire cuirass, made with a board cut in an outline of the body and plaster-of-Paris. The child is laid on the board, and then the whole enveloped with plaster-of-Paris bandages from the foot to the axilla. The plaster is then cut away in front, the interior comfortably padded, and the patient held in place by lacings or bandages. Extension and fixation in bed are to be continued until the active symptoms and the deformity have entirely disappeared, and the spasm of the muscles is no longer present. Adults are then given crutches, and a portable splint which has a perineal crutch, extension by adhesive plaster, an abduction bar, and an upper (thoracic) ring to prevent flexion and extension at the hip. Children, after treatment in bed, are to have the portable bed, and then the portable splint, with or without the high shoe and crutches.

DR. J. RIDLON was much pleased to hear the author

of the paper take the ground that hip cases should be cured without deformity. He recalled a case of a patient in whom the muscular spasm had been relieved by pinching the muscle. The child was very thin, and it was found that when the adductors were separated from the other muscles and the belly of the muscle was pinched without any attempt at fixation, there was as much relief as could have been afforded by lateral traction.

Dr. Shaffer said that the paper had suggested to him the importance of separating in our minds the disease from the deformity. It is a question how far we are justified in meddling with the deformity, which is simply an expression or, so to speak, a symptom of the disease. In his experience attempts at speedy reduction of the deformity had been followed by disastrous results. Nature gives a very positive indication in the acquired position of the thigh—that in which the immobilization of Nature reaches its maximum, and the diseased parts receive the greatest relief from reflex muscular spasm. If we forcibly interfere with this effort on the part of Nature, we inflict a distinct traumatism.

On the threshold of treatment the important question is, not whether traction is to be made in the line of the shaft or the neck, but how to secure an artificial immobilization in the position Nature assumes as the one that affords the most protection to the inflamed parts. He believed that if the joint were protected from traumatism—in other words, if traumatic contact of the inflamed joint surfaces is removed, and this can readily be done by the use of portative apparatus without entailing immobilization of the entire body from the head down—the joint is placed in the best known local condition.

The portative traction treatment is compatible with fresh air, sunlight, and moderate exercise, which are the best means of combating the tubercular disease and the tubercular diathesis. More lives have been saved and better results have been thus secured, than by any other method which has been thoroughly tested.

Dr. R. H. Sayre agreed with Dr. Shaffer as to the importance of maintaining the general health, and the inadvisability of general immobilization of the body, if the diseased joint could be controlled without it. He thought that complete immobilization of the hip-joint in young children was very difficult to secure; and that the movement that stopped short of producing muscular spasm and pain was not harmful. For poor children particularly, he thought the portable bed was an admirable contrivance. The relief obtained in some cases by pinching the muscle could be explained on the supposition that it stopped the reflex action of the muscle. It is known that firm constriction of the belly of a muscle will, in certain cases, abolish spasm.

Dr. Charles L. Scudder, of Boston, advocated a more frequent resort to the results of experiment on the cadaver. He recalled Dr. Bradford's experiments made in 1880, in which it was found that in an adult a force of one hundred pounds was not sufficient to separate the head of the femur from the socket; while in the shallow and yet not completely ossified acetabulum of a young child, a moderate force causes separation, and less force was required in the fœtus. Dr. Scudder believed that in hip disease of children, a tractive force of from three to five pounds would separate the joint surfaces, as was illustrated at the Children's Hospital in Boston in the case of a young boy who had hip disease and night cries. The joint cavity was opened and a small quantity of pus evacuated. While the boy was under ether, it was found that traction made with the hand separated the joint surfaces to such an extent that the finger could be placed between the head and the acetabulum.

Dr. Hubbard thought that no one at the present time held the opinion that ankylosis is caused by immobilizing the joint affected with chronic inflammation. He had found it difficult to get ankylosis in cases where it was desirable, as in disease of the knee. The first object is to give rest to the joint, which is best done by traction; not to separate the surfaces, but to overcome articular pressure which leads to muscular spasm. He believed the long hip splint gave sufficient immobilization for all practical purposes. It is more easily managed than the portable bed of Dr. Phelps, which from neglect would be likely to cause excoriations. As the disease seems to be a struggle between the tubercle bacilli and the vitality of the organism, he thought it especially important to place the system in the best possible condition to resist attack. He had rarely seen constitutional disturbance from abscesses which had been let alone, although, in exceptional cases, acute and painful conditions are certainly greatly relieved by surgical interference.

Dr. Judson commended the title of the paper. It was an admission that hip disease is not to be cured by treatment, but so managed that the almost inevitable recovery by natural processes should be with the minimum of disability and deformity. He thought that more emphasis should be placed on the importance of protecting the joint from the traumatisms of standing and walking, as is done by the use of Hutchinson's extra long crutches and high sole on the well foot. But in every case there are long periods of exemption from pain, when this simple apparatus will be discarded. The ischiatic or perineal crutch of the hip splint, however, cannot be wilfully discarded; and when it is seen that the rack and pinion not only furnish traction, but also a convenient means of adjusting the length of the upright, the hip splint appears to come very near perfection as an instrument for the management of hip disease. He had never recognized either the trauma said to be caused by reflex muscular contraction or the alleged mechanical counter-action of the muscles by traction. He believed, and had always held, that the hip splint mitigates reflex muscular contraction by allaying the inflammation which gives rise to it. This it does by arrest of motion and prevention of pressure; motion being arrested by traction brought about by the use of the key, and pressure being averted by the perineal or ischiatic crutch, which makes the limb a pendent member. As the inflammation is resolved the reflex muscular contraction ceases.

The last annual report of one of our orthopædic institutions contains a table, from which it appears that there have been under treatment 371 cases of disease in the hip; 6 in the shoulder; 85 in the knee; 3 in the elbow; 27 in the ankle; and 5 in the wrist; an aggregate of 483 in the lower, and 14 in the upper extremity. Shall we draw the inference that the incipient osteitic focus is found only or chiefly in the cancellous tissue of the lower extremity, or that a focus in the upper extremity more readily undergoes resolution by reason of its comparative exemption from violence? If the latter view is correct, it follows that the limb is to be made a pendent member

by the persistent use of the axillary or ischiatic crutch at the earliest recognition of the disease. In some cases, an early diagnosis may be facilitated by the following simple method: Let the patient sit on a table with the legs hanging and the knees separated; in this position, swinging the leg laterally is possible only with rotation of the femur; and if one leg oscillates in a less arc than the other, it induces or confirms a suspicion of the integrity of the joint.

He did not believe in treating abscesses and sinuses excepting indirectly through the general and local management of the bone disease in which they have their origin.

DR. GIBNEY was in favor of securing absolute immobilization, but sometimes he would rather have less perfect immobilization, if by so doing he could secure a change of air and climate, with the consequent improvement in the general nutrition. Ordinary hip disease is managed satisfactorily by the portable traction splint, with or without the rack and pinion; and he had been agreeably surprised with the facility with which these patients ran around in the tenement houses. They come to his clinic only every three or four weeks for adjustment of the apparatus; and during these intervals engage in the most active sports; they certainly do not lie in bed in dark rooms and die of pyæmia. It is unsafe to put these children in an appliance like a cuirass or the portable bed, unless one is certain of being able to see and attend to them at short intervals. It had been his lot to see cases in which he had been unable at times to obtain proper coöperation on the part of the patient's family. He had often seen abscesses burrowing up to the spinal column and down to the knee; and such cases seemed to baffle even attempts at surgical interference. We must be guided a good deal by circumstances, and if we can protect the hips from trauma and give the patient the benefit of out-door exercise, abscesses will generally be insignificant. He believed in correcting the deformity speedily, if necessary by dividing tendons and bone under an anæsthetic; for by so doing we save much time and lose nothing.

In regard to aspirating the joint over-distended with fluid, it was almost impossible to diagnosticate an over-distended hip-joint. The position of the limb does not depend on the quantity of fluid in the joint, but it is due to reflex spasm, and the efforts made by the child and nature to secure fixation.

DR. J. H. GIRDNER described an experiment on the cadaver in which great force was applied without separating the surfaces of the hip-joint. He also cited a case in which it had been necessary to keep the hand applied to the face for nine weeks in the course of a plastic operation on the nose. At the end of this time, there was no limitation in the motions of the elbow and the wrist.

DR. KETCH believed that hip disease is so often characterized by exacerbations that all attempts at a division into stages are of no practical value. He thought that the hip splint could be often of use for the reduction of deformities even in those periods when the patient is confined to his bed. In general, he believed it was a great mistake to make use of any apparatus which can be entirely left to the care of the patient or family for long periods. The explanation of the relief of pain by compression of muscles was to be found in an involuntary action on the part of the patient which secures fixation and traction at the same time.

DR. BERG, speaking from the standpoint of the general practitioner, who frequently saw children in the very beginning of hip disease, related the histories of three cases which had presented the symptoms of early hip-joint disease and yet recovered perfectly after rest in bed for a few weeks. He now insisted on all such patients remaining in bed for several weeks before commencing any other treatment.

DR. PHELPS, in closing the discussion, said that many cases in tenement houses, whether treated by the long traction splint or by the portable bed, are deplorably neglected; but this does not argue against the use of either apparatus; it simply illustrated one of the difficulties with which all practitioners have to contend. He valued the portable bed because he desired immobilization of the affected joint, and this could not be obtained with splints having joints in them, and not including the trunk. He could relieve his patients better in bed during the period of deformity, and so adopted this method of treatment. He had seen patients in England who had been in bed several years, and were still in excellent health. He did not, however, advocate prolonged bed treatment. Believing that the cases in question are inoculations of the bacillus tuberculosis on a previously inflamed surface, and not instances of constitutional tuberculosis, he explained the frequency of tubercular joint disease in the lower extremity, by the statement that the joints of the lower extremities being more subjected to traumatic inflammation, furnish good ground in which the bacillus of tuberculosis could more readily reproduce itself.

He had presented his honest convictions, and hoped to report his cases later in such a way that others could disprove his statements, or he could substantiate his views.

THIRD CONGRESS OF THE GERMAN SOCIETY OF GYNECOLOGY.

Held at Freiburg, June 12, 13, and 14, 1889.

(Specially reported for THE MEDICAL NEWS.)

(Concluded from page 190.)

ABSCESS OF THE PELVIS.

DR. WIEDOW said that in extra-peritoneal abscesses, one always meets with fluctuation which is not found in abscesses of the peritoneal cavity. From a clinical point of view, these patients have fever, and a fever with remissions as in pyæmia; they are anæmic, and suffer alternatively from constipation or diarrhœa. The abscess may burst and evacuate itself into the peritoneum, and prove rapidly fatal. The opening of such abscesses externally is generally followed by fistulæ. He thought these abscesses ought to be operated upon as soon as the diagnosis is made. Three kinds of abscess exist: the subcutaneous and submucous abscesses, the deep abscesses, and the fistulous abscesses. In the first class of abscesses, an incision followed by drainage is the only procedure required. The deep abscesses which can be easily reached, can be opened directly and drained by the vagina, such as an abscess of the peritoneal cavity. If we have to deal with a deep abscess that cannot be reached by the ischio-rectal fossa, or if situated

near the rectum, he thought it more advantageous to make, according to Hegar's method, a plastic resection of the sacrum. The skin is first incised in a V shape, then the sacrum is freed from its attachments and sawed through to the peritoneum of the posterior surface; this flap is then lifted and one can easily reach the abscess, which can be drained and easily irrigated; on a level with the Fallopian ligament, the peritoneum must be detached before the abscess is emptied.

DR. ELISCHER had observed on several occasions, that when abscesses of the pelvis were not opened early an amyloid degeneration of the kidneys followed; hence, he believed these abscesses ought to be evacuated as early as convenient.

DR. HIRSCHBERG, of Frankfort-on-the-Main, in a case of tumor of the pelvis which could not be reached by the vagina, made an examination of the patient under chloroform and found a fluctuating tumor; the tumor was punctured through the rectum and about ten ounces of pus were obtained. The tumor having returned to its original form, he made a new puncture; then, by means of the polyp forceps, he introduced a drainage-tube which was left in position for two or three days, and the patient was cured.

DR. WIEDOW thought it dangerous to puncture an abscess through the rectum, as one could not know how far the upper wall of the abscess reaches, and pus could be introduced in this manner into the peritoneal cavity.

ON THE ULTIMATE RESULTS OF EXTIRPATION OF THE UTERUS.

DR. MUNCHMEYER, of Dresden, said that at the obstetrical clinic of Dresden, from 1883 to 1889, there had been performed 110 extirpations of the uterus, of which 80 were for carcinoma and 30 for other diseases. Out of the 80 operated on for carcinoma 4 died from the immediate effect of the operation—that is, 5 per cent.; 1 died from strangulated hernia, 2 from septicæmia, and 1 from peritonitis. Out of these 80 operated upon, 10 died from a recurrence of the disease, 4 of intercurrent affections, while others have one recurrence. 41 who have been operated upon during this past year have had no return of their trouble, and in 17 women operated upon two years ago the cancer has not reappeared. Amongst this last series 3 have had no recurrence for three years, 1 for four years, and 1 for five years.

He thought it very important that the operations should be performed as early as possible. Out of the 30 other extirpations, 17 were for myomas, 5 for prolapse, 5 for severe nervous troubles, 3 for diseases of the annexes of the uterus. Most of them were operated on by the vaginal method, or supra-vaginal. The vaginal method leaves patients in a state in which they are less liable to take cold, and, on the other hand, certain women cannot resist an abdominal incision, which is due to a weak state of the cardiac function. Out of 110 extirpations of the uterus there were only 6 deaths—that is, 4.5 per cent.

DR. FREUND, of Strasburg, extirpated a carcinoma of the neck in 1878 by laparotomy, and his patient is still alive. As far as he knew, it was a unique case.

DR. LEOPOLD did not think the new methods of extirpation of the uterus so advantageous, and he did not find that in extirpation *per vaginam* that we work in the dark. Even where the vagina is very narrow, as in virgins, it requires only two deep lateral incisions to have all we desire before us; as to the arteries, they can be felt.

DR. HEGAR said that it was not the narrowness of the vagina which had most troubled him, but the utero-sacral ligaments.

ON POST-PARTUM HEMORRHAGE.

DR. DÜHRSSEN, of Berlin, said that, according to the statistics, there dies in Prussia every day a woman by hemorrhage following labor. He thought that the easiest manner to diminish the mortality was to plug the parts. The plugging is a hemostatic process; it produces uterine contractions, instead of preventing them; moreover, it acts by compression on the uterus and vagina. Plugging will succeed when massage, hot water, etc., have given no results. It acts surely in uterine inertia and brings about powerful contractions. In cases of placenta prævia direct compression arrests the blood, but this manual compression can be replaced by a plug.

DR. DOHRN, of Koenigsberg, had used plugging with the iodoformed gauze in a case of atony after Cæsarean section; immediately the contractions returned, and the operator was able to go on carefully with his suturing. No septicæmia need be feared if the substances which form the plug have been dipped for five minutes in boiling water. Iodoform gauze can be used in 10 or 20 per cent. strength, or, again, absorbent cotton or linen dipped in a carbolic acid solution, 3 per cent., so as to destroy all the germs which could be found in the uterus.

DR. OLSHAUSEN thought that the important part in hemorrhages occurring after labor is to diagnosticate rapidly the source of the hemorrhage, and to know whether we have to deal with a case of atony of the uterus or a tear of the neck. Hemorrhages from the neck are quite frequent, and difficult to diagnose, especially when we have placenta prævia. He was not in favor of hot water in ruptures of the neck, for by this means we remove the clot every time it is formed. As to the plugging in uterine inertia, he did not think it a very rational process, for the plug prevents the uterus from contracting. If Dührssen has had fifty-seven cases which proved successful, he also has had failures; he knew two cases which occurred in the hands of his assistants, who were quite practical men. The best means to deal with uterine inertia is by the bi-manual massage of the uterus.

DR. FEHLING was of the opinion of Dr. Olshausen, and thought that plugging of the uterus brings about an anti-physiological state, as, in the normal state, there is no cavity in the uterus.

DR. DOHRN said that in four cases of uterine inertia in which he had tried everything without success, he finally used plugging, and obtained immediate hemostasis. In a fifth case, for uterine atony during Cæsarean section, plugging brought on immediate contraction of the uterus. He was, however, of the opinion of Dr. Olshausen, and thought that the diagnosis of the seat of the hemorrhage ought first to be made.

DR. STOEPPER, of Mannheim, had for the past twenty years used bi-manual massage, with perfect success.

DR. KUSTNER said that in his region old women are in the habit of pulling on the cord, so that he often met with uterine atony and often had the opportunity to

practice plugging with iodoform gauze. He had seen, in Jena, a case of death by hemorrhage due to an aneurism seated at the placental insertion; if plugging had been resorted to, the woman would certainly not have died.

VENTRO-FIXATION OF THE UTERUS.

DR. KUSTNER thought that in retroflexion of the uterus the method of Schultze gives better results than ventro-fixation. In a case of ventro-fixation for an interstitial myoma, he produced an abortion at the third month. He had treated forty-six retroflexions by Schultze's method; in nineteen cases he had to deal with adhesive retroflexions.

DR. FROMMEL thought that ventro-fixation ought to be practised only after having tried more conservative methods.

DR. SÄNGER had operated on twelve cases of ventro-fixation; one of his operated patients is now pregnant in the sixth month; she has a few pains, and her physician keeps her in bed. In all the cases he had operated upon the uterus was movable.

DR. KUSTNER thought that the suture of the uterus to the parietes prevents the expansive movement of the uterus during pregnancy.

DR. HEGAR once did this operation at his clinic, but the uterus became detached.

The next Congress of the German Society of Gynecology will be held in Bonn, in 1891.

CORRESPONDENCE.

A WINTER VACATION TO THE WINDWARD ISLANDS.

III.

ON deck by seven o'clock in the morning, and before us lay the shore of the Island of Guadeloupe; past mighty mountain, bold headland, and cosy bay we steamed for about three hours. On the slopes of the hills and in winding valleys were wide stretches of light-green cane fields. Stately sugar mills and comfortable planters' houses were thickly scattered about. As we steamed past, the island appeared more prosperous than any we had yet seen. The French bestow more care on their West Indian possessions than the English or Danes. Large enterprises prosper. The most extensive cane sugar factory in the world, so said, is located at Besse Terre, and formed one of the chief attractions of our visit. Green cane enters at one end and is delivered at the other in the form of dry sugar in bags in about six hours. Cane is sent to the mill from long distances about the island at a great saving to the planters. A large amount of rum is manufactured at this mill. I was told that this company purchased a large share of the rum made in the Islands in addition, which is sent to France, and after undergoing a manipulation peculiar to the trade reappears in the market in the form of French brandy. The language is French exclusively. More business appeared to be going on than in any place we had yet visited. The stores were numerous and well stocked with goods of French manufacture. We visited a natural history museum very complete in its collection of the flora, fauna, mineral and cultivated products of the island. A department of the collection that was especially attractive consisted of the native woods. Large specimens in cross and longitudinal section were shown. They were susceptible of high polish, and the grain and coloring of many of them were very beautiful.

Mr. H. left us at this place, very much to my regret. I think I had nearly pumped him dry of his abundant stock of information about the West Indies; but justice requires me to state that he was always ready to impart his well-arranged facts. I wish I had space to repeat a story of his about a voyage to Pensacola from St. Thomas in a schooner with an insane captain. It was one of the most blood-curdling stories of personal adventure I ever listened to. Here is one story at his expense that will bear telling. When he arrived at Basse Terre he found a large consignment of staves and barrel heads piled up on the landing under quite a large port-charge which had been refused by the consignee on the ground that there were no bungs sent with them. Can one imagine anything less complete in the eternal fitness of things than a barrel without a bung? But there he was, and nothing could get him out of the scrape but an equivalent number of bungs.

It was interesting to observe the marked difference in physical traits between the French negro half-breed and the English. The latter is thick-set, burly, the light-hearted look of the pure African blocked out, giving place to a surly, brutish expression. The French cross gives a breed of finer lines. The women are slender, petite, clean—a thing of pleasure and song. The men are small, lean, elastic, and altogether a better race to live with. The intermixture, in the towns at least, appears to be the rule, a pure-blood negro being the exception; while in the English Islands the reverse is true.

Our arrival at Guadeloupe was signalized by quite a rare event. The most conspicuous object as we neared land was the cone of Soufriere, a volcano nearly 5000 feet high. For the first time in six months it was without a cloud. The crater was clearly visible clad in green to the excoriated edge, beyond which we could see a vast rent, the result of the eruption of 1840, when it was last active. At that time the island suffered severely. A large volume of smoke poured out of the summit near the margin of the recent fracture, and blew out horizontally a dark streak across the sky. Soufriere was smoking her pipe, as the natives say. From the sea the mountain appears difficult of access. From the land side it is but a prominence in a central spine of mountain that lies parallel with the long axis of the island. One of the results of the last eruption was an earthquake which shook down many of the buildings at Besse Terre, and among them the cathedral. It has been rebuilt after a manner called earthquake-proof. It is constructed of iron with an outside veneer of stone. Throughout the interior huge rivets and bolt-heads may everywhere be seen covered with white paint. It may be earthquake-proof, but I doubt it.

We left in the afternoon, and as we steamed out to sea we took another look at Soufriere. She was covered with a mass of towering cloud, and was smoking her pipe after her usual manner, with her face hidden from the gaze of man in shadows and tears.

The next morning we were snugly lying tied up at a wharf at St. Lucia. It is the finest harbor in the Islands. The English Government is now transferring its naval

station from Barbadoes to Castries, as the town is named. Forts were being built, black troops drilled, steam dredges at work and coal accumulating in large mounds. Hills, terminating in sharp cones, surrounded the bay and town. The town did not appear to have any white inhabitants except the military, and was entirely without interest. We always set up the camera in the market-place of each town as a point to secure characteristic views. The market-place is generally the principal square, and unfortunately the buildings were all alike—an open shed, or a number of them, with corrugated iron roofs. There is something about iron, however it is employed architecturally, that is fatal to the picturesque. Often the groups of people were enough so to compensate for the defect in the buildings. The sales were made by women, each one squatting over a little pile of yams, cocoanuts, or fish, bread, or cake. The noise was deafening. They appeared to be quarrelling, but it was only a friendly dispute over prices. Cooking was always going on over little charcoal fires, the pots or fryingpans supported on a couple of stones. Charcoal is the fuel, each day's supply being bought at the market.

At sea again in the afternoon. Shortly before sundown we passed one of the most remarkable sights of the Islands. These are the Pitons of St. Lucia. Two mountains rising out of the sea at the land's edge, side by side, perpendicular, like obelisks of indescribable grandeur, 3000 feet high. No near approach of the interior mountains detracts from their proportions. A span of about 800 yards separates them, with a little bay between. The surf piled up grandly at their base. Dark gray, brown, verging into black, appeared the general color, with streaks of red and irregular patches of green where creeping plants and shrubs had found root. It appeared madness to attempt to climb them, yet it is said that four sailors from the English fleet had made the attempt. After getting up a few hundred feet one of the men lost his grip upon the rock and fell; a few hundred feet higher a second dropped, still higher a third, and the fourth man, who had nearly reached the top, seemed to grow faint and fell. No one ever knew the cause, but they were supposed to have been bitten by the fer de lance, that is believed to make its home in the Pitons. St. Lucia, like Martinique, is infested by this terrible serpent. It belongs to the rattlesnake family, but the latter is as harmless as a babe compared to it. Agile, powerful, quick to rage, with a disposition to attack and pursue, it is the most deadly of the serpent enemies of man.

St. Lucia is beautiful. The mountains are many of them inert volcanoes. From one ragged peak a thin line of smoke drifted across the sky. But the beauty was repellant, such us one might fancy would be that of a fallen angel. The forests were so dark and impenetrable, the mountains so fantastic, and the valleys, dark and profound, were too much like rents in the face of Nature to leave a pleasant memory. One could make studies here for illustrations to the Inferno. The sea off St. Lucia is of a blue so deep and prismatic that it is the latter quality alone that prevents its being called black rather than blue. With the gloom of St. Lucia and the blue-black of the sea, it seems like a world in mourning. It was off the Pitons that Rodney fought and won the great battle with the Count de Grasse that restored to England her possessions in the West Indies.

Our next stop was made at Barbadoes. I found but little to interest me there. Everything appeared prosperous. Carlisle Bay was full of shipping, among them half a dozen English men-of-war. The proper thing to do when one has a day at Bridgetown is to take the little railroad fourteen miles long to Craine's Hotel, on the eastern side of the island, and look at the surf. The island lies at the outer edge of the group, and takes the full buffet of the waves of the vast middle Atlantic. The war here between sea and rock is eternal. The island had considerable interest as being the most densely populated to the square mile on earth. So densely crowded is it that the negro cannot squat on a little patch of land, but is obliged to work. Hence, Barbadoes may be said to be the only exception to the ruin that has overtaken the other Islands. Two or three days in a week is all the work to be had out of the negro throughout the Islands. Between two such deadly enemies as bad labor and beet-root, the poor sugar planter has come to grief.

Another night at sea and a glorious surprise at St. Vincent. Kingstown, with its red roofs showing through a forest of palms, lies in the embrace of its infolding hills draped in forest from shore to crest. Beyond were volcanic-shaped mountains, each with its Tam o' Shanter of cloud. Here were said to be craters and lakes, cold, green, and mysterious. The sides were carved into deep ravines that twisted into the dark, green depths and gave exquisite variations in color as fragments of cloud trailed their shadows after them. It would be difficult to conceive of a more exquisite picture than that of town and island from the deck. I dreaded to go ashore lest I should be disenchanted, and I was.

The chief attraction of the town is Ja-ja, an African king from the West Coast. He refused to make a treaty with the English government, and was accordingly persuaded that a voyage on a gunboat to St. Vincent, and an abode there for the rest of his life, would very materially promote his health. He has a liberal income of £1000 from government, a house to himself, horses, servants and dogs. He came off to the ship and had luncheon. The captain fired a salute and had the crew drawn up to receive him. He enjoyed the honors paid him greatly. He is very fond of Captain Hubbard, who always pays him great attention. His tribe are said to be man-eaters. His Majesty appeared very benevolent and mild, so that it was hardly possible to believe that the nice-looking, middle-aged African gentleman would eat you. I have no doubt that if the fortunes of war were to render that event possible, that he would proceed to the feast with every consideration for your feelings. He is allowed to have but one wife with him at a time, out of consideration, I suppose, for the high state of morals existing on the island; but there is a rotation in office about twice a year, which in a measure compensates. When he goes out a white police sergeant trots at his heels, who appears very much lower in the social grade than the poor savage. Surely there is a divinity that doth hedge a king.

I was surprised at the number of drug stores to be seen in the town; the same being true of all the Islands. The amount of patent medicine consumed by the colored people is enormous. To purchase a bottle of some compound costing a dollar confers quite a social distinction. I may state another thing that suprised me when I heard of it, namely, that a very extensive business in life insurance is done among these people, nearly all the great

companies in the States having agents travelling about among the Islands. They pay an extra premium here, but even then it does not appear a very safe investment, unless it is done on the theory that the insured is not expected to pay more than his first premium when he allows his policy to lapse. In fact, it is hard to understand how he would raise the money to pay more. It is not because he is such an exemplary husband and father that he so readily discounts the future, as the policies are all small endowments for short terms.

Ely Van de Warker.

NEWS ITEMS.

The Annual Meeting of the Association of American Physicians will be held in the Army Medical Museum, Washington, on September 18th, 19th, and 20th, under the Presidency of Dr. Francis Minot, of Boston. The programme has just been issued and contains the following papers:

The President's Annual Address, by Francis Minot, of Boston.

The Early Stage of General Paralysis, by C. F. Folsom, of Boston.

Tetany, by James Stewart, of Montreal.

Tetany and a New Theory of its Pathology, by John T. Carpenter, of Pottsville.

Thrombosis of the Cerebral Sinuses and Veins, by A. B. Ball, of New York.

Chylous Effusions into Serous Cavities, by S. C. Busey, of Washington.

Substitutes for Opium in Chronic Diseases, by J. F. A. Adams, of Pittsfield.

Remarkable Case of Slow Pulse, by D. W. Prentiss, of Washington.

Discussion on the Relation between Chlorosis, Simple Anæmia, and Pernicious Anæmia, including Leucocythæmia and Hodgkins' Disease. Referee, Frederick P. Henry, of Philadelphia; co-referee, F. Forchheimer, of Cincinnati.

Primary Cancer of the Duodenum, by E. N. Whittier, of Boston.

Primary Cancer of the Gall-bladder and Ducts, by John H. Musser, of Philadelphia.

Gastric Neurasthenia, by G. M. Garland, of Boston.

Specimens from Two Cases of Cretinism, by W. F. Whitney, of Boston.

The Anatomical and Physiological Relations of Lesions of the Heart and Kidneys, by H. F. Formad, of Philadelphia.

The Contagium of Diphtheria, by P. Gervais Robinson, of St. Louis.

A Supplementary Inquiry into the Frequency with which Lead is Found in the Urine, by James T. Putnam, of Boston.

Discussion on the Relations of Rheumatism to Rheumatoid Arthritis. Referee, William Osler, of Baltimore; co-referee, Morris Longstreth, of Philadelphia.

How Far may a Cow be Tuberculous before the Milk becomes Dangerous as a Food Supply? By Harold C. Ernst, of Jamaica Plain.

The Bacillus Tuberculosis, by J. T. Whittaker, of Cincinnati.

Hot Air Inhalations in Tuberculosis, by E. L. Trudeau, of Saranac Lake.

On Thursday evening, September 19th, it is proposed that the Association shall have an Annual Dinner.

The Statutes of Tenth International Congress, Berlin, 1890.—The following statutes of the Tenth International Medical Congress have been announced.

Article I. The Tenth International Medical Congress will be opened on Monday the 4th of August, 1890, and closed on Saturday the 10th of August, 1890, in Berlin.

II. The Congress will consist of approved physicians who have registered as members and who have given in their card of membership.

Members will pay a registration fee of twenty marks (about $5.00), for which they will receive a copy of the transactions of the Congress as soon as they are published. The date for the registration of members will be determined later.

III. The objects of the Congress are purely scientific.

IV. The work of the Congress will be divided into sections. When registering the members should intimate with which section they desire to associate themselves.

V. Each section will have a chairman, three vice-chairmen, an undetermined number of honorary chairmen and secretaries.

VI. Further information regarding the general sessions and the sessions of each section will be published later.

VII. The general sessions will include proceedings relating to the congress in general, and addresses and communications of general interest.

VIII. The work of the sections is being formulated.

IX. The addresses before the general session will be determined by the organizing committee.

Proposals regarding the work of the Congress should be sent in before July 1, 1890, to the organizing committee, who will determine whether such proposals be accepted or not.

X. All addresses and communications must be sent to the secretary before the close of the session. The editorial committee shall determine to what extent or in what length such articles shall be printed in the transactions.

XI. The official languages of all the sessions will be German, English and French. The statutes as well as the programmes will be printed in all three languages.

XII. The time allowed for introductory addresses in the sections will be limited to twenty minutes. Discussions will be limited to ten minutes.

XIII. The acting chairman shall have charge of their individual sections subject to the general rules.

XIV. Students of medicine and men and women who are not physicians may be invited by the chairman to seats in the audience, or permission for their admission may be secured from the chairmen.

XV. Communications or questions in the several sections should be addressed to the respective chairmen. All other communications to the general secretary.

The Prophylaxis of Tuberculosis.—The report of the Commission appointed by the Congress of Tuberculosis to investigate tuberculosis in man and animal, the dangers of using tuberculous milk and meat as food, and also the dangers of the spread of the disease by means

of infection, was read before the Academy of Medicine of Paris on the 31st of July.

The Commission was a most able one—being composed of the following: Drs. Chauveau, Butel, Cornil, Grancher, Landouzy, Lannelongue, Legroux, Leblanc, Nocard, Rosignol, Verneuil, Villemin, and Petit. The report was received and approved by Drs. Bouchard, Brouardel, Potain, and Proust, all members of the Congress on Tuberculosis. Their report is as follows:

I. Of all diseases, tuberculosis claims, both in city and country, the largest number of victims. In 1884, a year chosen at hazard, for example, there were 56,970 deaths in Paris, and of these about 15,500—over a quarter—died of tuberculosis. Pulmonary phthisis is not the only manifestation of tuberculosis, as is generally thought by the public. Physicians have discovered that many diseases may be due to tuberculosis, among others, bronchitis, colds, pleurisy, scrofula, meningitis, peritonitis, enteritis, tumors, osseous and articular lesions, cold abscesses, etc. All these may be directly caused by tuberculosis, and their utimate prognosis is no more hopeful than that of phthisis pulmonalis.

II. Tuberculosis is a parasitic, virulent, contagious, and transmissible disease, caused by a microbe—*the bacillus of Koch*. This microbe can penetrate into the organism either through the digestive tract, by means of food, or through the lungs by means of the inspired air, or through the skin and mucous membrane by means of abrasions, punctures, wounds, or ulcerations. Certain diseases, such as measles, smallpox, chronic bronchitis, and pneumonia, and certain constitutional conditions, due to diabetes, alcoholism, syphilis, etc., greatly predispose the contraction of tuberculosis. The causes of tuberculosis being known, the precautions taken to prevent the entrance of the germs into the body are capable of preventing its propagation. We have an encouraging example in the results obtained in typhoid fever, in which the epidemics diminish in all towns where the necessary measures are taken to prevent the typhoid germ from mingling with the drinking-water.

III. The parasite of tuberculosis may be found in the milk, muscles, and blood of animals which serve as food for man (ox, cow especially, rabbit, poultry). Raw meat or underdone meat and blood being capable of containing the living germ of tuberculosis, should be prohibited. Milk, for the same reason, should only be consumed after having been boiled.

IV. Owing to the danger arising from milk, the protection of young children, who are peculiarly predisposed to the contraction of tuberculosis (over 2000 children under the age of two years dying annually of tuberculosis in Paris alone) should specially demand attention of both mothers and nurses. The ideal food for the infant is the milk of a healthy woman. The tuberculous mother must not nurse her child, but should confide it to the care of a healthy nurse, living in the country, where, under the best hygienic conditions, the risks of contagion from tuberculosis are much less than in town. The child thus brought up will have the best chance of escaping tuberculosis.

If nursing at the breast is impossible, the infant may be fed artificially upon cow's milk by means of the bottle or spoon; the milk must, however, always be boiled. Unboiled milk of asses and goats is infinitely less dangerous.

V. Owing to the dangers arising from the meat of slaughtered animals, which may preserve all the appearances of health even when tuberculous, the public has every interest in being assured that the inspection of meats, as required by the law, is being properly and generally practised. The only certain method of avoiding the danger of meat coming from tuberculous animals, is to cook it to such an extent that the interior portions are as well done as the surface. Only thoroughly roasted, boiled, or fried meat is entirely devoid of danger.

VI. On the other hand, the germ of tuberculosis may be transmitted from the human tuberculous subject to the healthy human subject, by means of the sputa, pus, dried mucous discharges, and all objects laden with tuberculous dust; it is necessary, therefore, in order to insure security from the transmission of tuberculosis, to:

1. Be known, that the sputa of phthisical subjects is the most formidable agent of transmission of tuberculosis; there is danger to the public in discharging the sputa upon the earth, carpets, hangings, curtains, napkins, handkerchiefs, clothes, and coverings.

2. Be well understood, that the use of spittoons should be imposed everywhere and by every one. These spittoons should be daily emptied into the fire and well washed with boiling water. They should never be emptied upon dust-heaps or in the garden, where they might lead to the infection of poultry, or in latrines.

3. Never sleep in the bed of a tuberculous subject; to occupy his room as little as possible; but, above all, do not allow young children to sleep there.

4. Remove from places or dwellings inhabited by tuberculous subjects all persons who may be considered as predisposed to the disease; the children born of tuberculous parents, those having had measles, smallpox, pneumonia, repeated attacks of bronchitis, or suffering from diabetes, etc.

5. Not to use articles which possibly may have been contaminated by phthisical patients (linen, bedding, clothing, articles of toilet, hangings, furniture, toys) except after thorough disinfection (high-pressure steam, boiling, sulphur vapors, or lime-washing).

6. Insure that the rooms of hotels, furnished apartments, cottages, or villas occupied by phthisical patients in watering places or winter resorts, are furnished and carpeted in such a manner as to render them capable of undergoing easy and thorough disinfection after the departure of each patient. It would be better if such rooms had neither curtains, carpets, nor hangings; but were washed with lime and the floor covered with linoleum. It is of the highest importance to the public that they should prefer the hotels in which such indispensable hygienic precautions and measures for disinfection are thoroughly carried out.

Dr. Dujardin-Beaumetz, in the discussion which followed the reading of the above report, said that on the whole he approved of the report of the Commission, but he must remind them that it was a mistake to think that tuberculosis was more frequent in towns than in the country. Exactly the reverse is true. Further, some of the statements made by the Commission were purely hypothetical and unsubstantiated by facts. Contagion by means of milk is absolutely exceptional. For this to take place, it would not only be necessary for the cow to be tuberculous, but also for her to be afflicted with tuberculous

mammæ. Again, the transmission of tuberculosis by tuberculous meat had not been proven. However, we know that the microbe dies in a weakly acid solution; hence the ingestion of tuberculous meat cannot be dangerous, since the contents of the stomach are acid.

M. DUCEMBERG thought milk from a tuberculous cow most dangerous.

DR. GERMAIN SÉE remarked that the Commission stated the possibility of the microbe entering the system through the air. This assumption he regarded as false. In the light set forth by the Commission, tuberculosis would, indeed, be nothing else than a pest. Koch had demonstrated that the tubercle bacillus cannot live in the air. It can only live and reproduce itself in the organism. Regarding the use of spittoons, he agreed with the Commission. As long as the sputa is kept moist there is no danger, but when dry it is different. Regarding the infectivity of tuberculous milk, he agreed with Dujardin-Beaumetz. To carry out the views of the Commission as to the use of raw meat, he thought impossible. Were all meat cooked according to the requirements of the Commission, little of it worth eating would be left. A temperature of 320° F. is necessary for the destruction of the bacilli. Meat is not eatable after having been subjected to a temperature much over 195° F. Moreover, it has been conclusively proved that the consumption of tuberculous meat is devoid of danger.

The further discussion of the report was adjourned to the next meeting of the Academy.

Johnstown Relief.—The joint committee on Johnstown relief of the College of Physicians and the County Medical Society requests that all members of sub-committees who have not yet made complete returns, should do so at once, and also send in their collection books for final settlement. The committee desires to close its accounts not later than September 1st.

Brown-Sequard's Testicular Liquid.—DR. BROWN-SÉQUARD describes the composition of the liquid as follows: To the blood of the testicular veins, semen and juice extracted from a testicle, crushed immediately after it has been taken from a dog or guinea-pig, he adds distilled water in a quantity which never exceeds three or four times their volume. The crushing is always done after the addition of water. The liquid is then filtered through filter paper or a Pasteur filter. For each hypodermatic injection he used nearly sixteen minims of the filtered liquid.

A Premium on Fecundity.—We quote the following from the *Lancet* of August 3d:

With the view of encouraging the multiplication of the French nation, the Chamber of Deputies have adopted a proposition made by Dr. Javal, to the effect that fathers or mothers of seven children should be exempt from personal or house taxes.

Prof. Alexander B. Mott.—The Faculty of the Bellevue Hospital Medical College desire to record in their minutes an expression of deep sorrow at the death of their associate, the late Professor Alexander B. Mott. Professor Mott was one of the few remaining members of the original faculty of the college. For twenty-eight years he had given his best efforts to the institution, of which he was one of the founders; and many thousands of alumni can bear testimony to the value of his teaching. Endeared to his colleagues by long and intimate association, his death is felt by each one as the loss of an earnest teacher, a good and a true friend.

AUSTIN FLINT,
August 15, 1889. Secretary.

NOTES AND QUERIES.

USE OF THE TESTICLES AS REINVIGORATORS.

To the Editor of THE MEDICAL NEWS.

The old saying, that "there is nothing new under the sun," is beautifully illustrated by the latest of Dr. Brown-Séquard's "discoveries." For over twenty years, to the personal knowledge of the writer, and probably for as many centuries, the Chinese have used the testicles of the sea lion for the purpose of stimulating the organs of generation in man and as a general nerve stimulant.

A great many sea lions are killed in the immediate vicinity of this place, principally for their oil; but the bristles, and penis with testicles, are sold to agents of the Chinese. The first-named are used for ornaments, but the last two articles are used by them as medicine. At times as many as one hundred and fifty are seen drying in the sun. When needed, a portion of a testicle is grated into a vessel, and an infusion is made which is administered *pro re nato*. Hoping that this may add something of value to the literature of this interesting subject, I am, respectfully yours,

J. T. MCCORMAC, M.D.
MANSFIELD, COOS BAY, OREGON, August 5, 1889.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM AUGUST 13 TO AUGUST 19, 1889.

By direction of the Secretary of War, a Board of Medical Officers, to consist of: ANTHONY HEGER, *Lieutenant-Colonel and Surgeon;* JOHN O. SKINNER, *Captain and Assistant Surgeon;* and JAMES C. MERRILL, *Captain and Assistant Surgeon*, will assemble at the U. S. Military Academy, West Point, New York, on August 25, 1889, or as soon thereafter as practicable, to examine into the physical qualifications of the candidates for admission to the Academy.—Par. 9, *S. O. 185, A. G. O.*, August 12, 1889.

GARDNER, WILLIAM H., *Major and Surgeon* (Washington Barracks).—Is hereby granted leave of absence for one month.—Par. 1, *S. O. 183, Headquarters Division of the Atlantic, Governor's Island, New York City*, August 13, 1889.

MATTHEWS, WASHINGTON, *Surgeon.*—Promoted to Surgeon, U. S. Army, with rank of Major, to take effect from the tenth day of July, 1889, vice Town, promoted.—*War Department, Washington, D. C.*, August 14, 1889.

HAVARD, VALERY, *Captain and Assistant Surgeon.*—Is granted leave of absence for one month, to take effect about October 1, 1889, with permission to apply to Division Headquarters for an extension of one month.—Par. 3, *S. O. 86, Department of Dakota, St. Paul*, August 10, 1889.

By direction of the Secretary of War, JOSEPH Y. PORTER, *Captain and Assistant Surgeon*, now at Jacksonville, Florida, will, if the state of his health will permit, proceed to Jackson Barracks, Louisiana, and report to the commanding officer of that post for temporary duty, and by letter to the commanding general Division of the Atlantic.—Par. 16, *S. O. 186, A. G. O.*, August 13, 1889.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL ARTICLES.

SOME OBSERVATIONS ON THE CAUSATION AND TREATMENT OF ASTHMA.[1]

BY BEVERLEY ROBINSON, M.D.,

PROFESSOR OF CLINICAL MEDICINE IN BELLEVUE HOSPITAL MEDICAL COLLEGE, NEW YORK.

FEW diseases have occasioned warmer discussions than asthma, on account of the obscurity which prevails in regard to its nature. By some it is regarded as a pure neurosis, capable of being excited in all sorts of ways, and often by the most trivial circumstance or change. For others there is scarcely such an affection as *nervous asthma alone* and independent of evident pathological changes in the chest, or in other regions of the body. From either point of view the essential part of the disease is the disturbed innervation of the bronchi, which is accompanied by paroxysmal dyspnœa. The spasmodic nature of the disease was admitted by Laennec and Andral in its early periods, because they were unable to discover in the chest sufficient lesions to account for the attacks of difficult breathing. Later the precise seat and character of the spasm of the bronchi was determined by Dr. C. B. J. Williams, by means of the artificial excitation to which the nerves of the bronchial tubes were submitted.

The anatomical and physiological facts in support of the spasmodic theory of asthma are: 1. The fact that muscular fibres are found throughout the extent of the bronchial divisions, even to the infundibula or air-sacs. 2. That these muscular fibres can be contracted to the point of closure under different kinds of stimuli.

Clinically it is supported by the facts: 1. That an attack of asthma may begin suddenly in an individual without evidences of any chest affection. 2. On account of the variety of the pathological lesions which precede or accompany it. 3. Because the pathological conditions are often mere sequelæ of long-continued asthma. 4. Because sometimes asthmatic attacks disappear although the chest lesion remains, and because no one of these lesions is always adequate to explain the asthmatic paroxysm. 5. The character of the asthmatic attacks resembles very much different nervous affections, like neuralgia or migraine; although many pathological conditions may tend to produce it, yet it is a disease apart, affecting the nervous system. 6. The great value of the administration, by the stomach, of the nitrites in the relief of asthma, as shown by Dr. Thomas R. Frazer, of Edinburgh, in his admirable clinical study of its cause.[1]

As opposed to the spasmodic theory, it is stated that the culmination after a paroxysm of asthma is marked by a profuse sero-mucous exudation accompanied by cough and expectoration (Bosworth). It is thought, therefore, that this theory should be abandoned. In its place, it is contended that the theory of Webber should be admitted. This theory is based upon the idea that the asthmatic paroxysm is not due to spasm, but to a paralysis of the vaso-motor nerves which regulate the calibre of the blood-vessels in the bronchial mucous membrane. Under the influence of this paralysis the membrane becomes suddenly swollen, and thus encroaches upon the calibre of the tubes and accounts for the dyspnœa in inspiration and in expiration, through reduction of the calibre of the air-passages and insufficient movement of air in their interior. It must be recognized, however, that the dyspnœa in asthma is also caused by insufficient contact of air with the blood-vessels in the pulmonary vesicles. This occurs when the air vesicles are filled with liquid or semi-liquid contents, as may and does occur in asthma brought on by preceding bronchitis.

My object, however, in this paper is not to debate theories of the asthmatic attack, but simply to make known a few clinical observations of interest in regard to its causation and treatment. During the past winter, while on duty at St. Luke's Hospital, several patients came under my care for the consequences of malarial infection. Amongst them four gave histories from which it was evident that asthmatic attacks accompanied frequently an outbreak of the poisoning. In these instances, also, the curative influence of anti-malarial treatment upon asthma, subsequent to the unsuccessful trial of ordinary medication for bronchial inflammation, was undoubted. I shall narrate the cases in brief terms:

CASE I.—W. L., forty-four, married, Englishman, house painter, now resides on Long Island, entered St. Luke's Hospital, October 22, 1888. Intermittent fever at fifteen years of age; again at thirty-two years. Four weeks previous to admission to hospital

[1] Read before the American Climatological Association, June 25, 1889.

[1] The American Journal of the Medical Sciences, October, 1887.

patient had a chill followed by fever and sweating. These attacks occurred daily for two weeks, and afterwards every other day. Patient is troubled with cough and wheezing whenever he has an attack similar to the one described. Patient has had a cough for the last three weeks, accompanied by irritation and tickling in the chest. About the time of the initial chills, patient has some difficulty of breathing and obstruction in the nasal passages. This lasted one week. Examination of lungs negative; spleen enlarged. Patient had chills and fever in the hospital. Microscopic examination of blood, on intermediate day of chill, revealed hæmatozoon malariæ. Patient relieved of chills, fever, bronchial and asthmatic manifestations by the use of quinine. Discharged cured, November 13, 1888.

Case II.—L. L., forty-two, single, Englishman, boat maker, was admitted to hospital October 3, 1888. Has had frequent chills and fever since last August. Contracted malaria in Costa Rica. Chills are usually quotidian. Patient had a chill followed by fever shortly after coming into the hospital. Examination of lungs negative, except a few bronchial râles. Patient "accuses dryness in throat and pain on swallowing, especially acids." A few days later, patient stated he was less choked up in his breathing and coughed less than on admission, but throat not less dry, particularly in the larynx. Nose somewhat obstructed by deviation of septum toward the left nasal passage anteriorly. In median portion of the nasal passage septum deviates to the right. In this region there is, also, more marked thickening of the pituitary membrane. Pharynx pale, thickened, œdematous looking, no mucus. In nasopharynx no mucus, pale, œdematous. Patient says cough is only occasional; spleen is enlarged.

October 8. No dryness, and absence of all symptoms in upper or lower air passages, which were present on admission. This result had been obviously obtained by the use internally of Warburg's extract. Discharged cured, November 30, 1888.

Case III.—A. J., male, thirty-four, missionary, admitted November 27, 1888. "Cough and constricted feeling in chest," obviously due to intermittent fever taken on West Coast of Africa. On examination, lungs negative. Discharged improved, December 3, 1888. Re-entered, January 6, 1889 (been well about three weeks). Last fourteen days "had cough and pain in chest." A few days previous to admission to hospital had chills followed by sweating—chill recurred the day before he came into hospital. Examination of chest showed "good resonance, a few moist râles, sibilant and sonorous râles." Treatment was anti-malarial.

Case IV.—J. G. P., thirty-six, married, clerk, admitted to St. Luke's, October 11, 1888. Has had tertian type of malaria for ten years. Several nights ago chills and fever began again; since that time repeated chills, followed, or not, by fever and accompanied by "difficult breathing and morning cough *without* much expectoration." Examination of lungs shows "hyper-resonant percussion note, sibilant and creaking râles, moist râles on cough." Patient dates his difficulty of breathing back to his first attack of chills and fever, but can trace no connection between the two. Patient was ordered to take Warburg's extract.

It seems to me that these cases show a very evident causative influence of malarial poisoning in producing bronchial irritation and asthma. In two of the cases ordinary expectorant mixtures were first employed without the slightest beneficial result following. The patients were treated with quinine, or Warburg's extract, and immediately improved.

In the case with partial nasal occlusion the anti-malarial treatment was equally efficacious, thus demonstrating that the nasal organ was not responsible for the asthma. In the different articles on asthma that I have read, I have found little or nothing said of malaria as an efficient cause. Humoral asthma is, of course, spoken of, and allusion is made to morbid conditions of the blood circulating through the system, and especially the nervous centres. Duclos, Bouillaud, and Trousseau were of this opinion, but thought that the morbid changes in the blood were the same that gave rise to gout, rheumatism, and hemorrhoids, and only caused spasm of the bronchi when the "peccant" matter was eliminated by this channel.[1]

In treatises or articles on malaria I find cursory allusions made to the influence of the miasm on the bronchial tract. Thus Liebermeister speaks of "a bronchial catarrh sometimes preceding the paroxysm, and manifesting an exacerbation at the moment of the outbreak."[2] Loomis[3] says, you may have a form of chronic malarial infection showing "itself in catarrhal inflammations affecting the mucous membrane of the stomach, intestines, and bronchial tubes. Patients have a form of bronchitis which is really a chronic malarial infection."

An analogous explanation to that offered by Dr. D. E. Keefe, in the *Boston Med. and Surg. Journ.*, of May 16th of the present year, to interpret the production of irregular œdema complicating malaria is probably equally good for my reported cases, *i. e.*,

"the poison of the disease acts on the nerve-centres, and through the sympathetic ganglia paralyzes the vaso-motor nerves, thereby dilating the bronchial arterioles, and thus causes an afflux of blood to this part."

And Dr. Keefe goes on to say what is really a translation of Webber's theory of asthma:

"This superabundance of blood the veins of the part find it more than usually difficult to return to the circulatory centre, in consequence of the congestion existing, ... and pressure on and narrowing of the lumen of the veins and lymphatics. In this manner stasis is undoubtedly produced, and may often be followed by transudation." This opinion, however, conflicts with Bosworth's affirmation,[4] for this author distinctly states that this condition "differs from inflammation in that

[3] Lectures on Fevers, p. 175.
[4] Trans. of Amer. Climat. Association, September, 1888, p. 179.

there is no tendency whatever to the escape of leucocytes."

There is another form of so-called humoral asthma which is not infrequently met with. The cases to which I refer are those forms of faulty secondary digestion in which this condition seems to account for the incitement of the paroxysms. In these cases the asthma is not occasioned directly by the presence of the food in the stomach, but later, when the veins have probably taken up the materials elaborated by the digestive process—and which in the asthmatic seem to stimulate unduly the hypersensitive pulmonary plexus. The blood, particularly in the gouty subject, seems to become readily charged with imperfectly changed and effete substances. This is an effect of deficient metabolism. It seems probable, in these cases, that not only the peripheral pulmonary nervous system, but also the central portion of it, is irritated unduly by the matters referred to. I have seen two such cases during the past winter:

Case V.—The first was that of an old lady, a widow, who suffered extremely at times from chronic rheumatic gout. When one or the other of her joints was most affected, she had no asthmatic seizure. When the pain left her joints, and she could hobble around with comparative comfort and freedom, she was apt to have a regular asthmatic seizure during the night. Lately the pains in the joints have improved, there is no asthma, but she has suffered from marked trigeminal neuralgia. Relief was found in the use of lithia water, saline cathartics, and iodide of potassium with occasional small doses of colchicum.

Case VI. was that of a distinguished New York lawyer, about fifty years of age, a bachelor, who has been a gouty subject for a number of years. This patient returned from Europe only last autumn, after a cure at Homburg. He had been very abstemious in his diet, had taken a fair amount of exercise, and considered himself in very good trim. One afternoon, in walking up town, he was suddenly attacked with dyspnœa which lasted over half an hour, or until some time after he reached his own home. During several successive afternoons the difficulty of breathing recurred at about the same hour and disappeared spontaneously, but perhaps somewhat more slowly. He then consulted me. Upon examination of the chest, I found nothing to account for it.

With very little reason for treatment in anything I discovered, I gave him some anti-dyspeptic combination of drugs. This medication proved wholly useless. I examined his urine with a negative result. Patient was finally given colchicine and a saline aperient each morning. A few days later the dyspnœa had disappeared and patient felt entirely well. At this stage, however, the urine showed a heavy deposit of urates and a large amount of uric acid.

It is evident in this case that the *materies morbi*, instead of acting on the joints, or on the skin, produced an irritation of the nerves of respiration and thus caused dyspnœa. It might have caused, as I have occasionally seen it do, coryza, or more extensive congestion of the upper air tract. Here we should recognize in the asthmatic development merely the symptom of a constitutional disease, which may manifest itself in a variety of ways. Gout and asthma are certainly, at times, both results of a common cause. As yet I am not aware that there is any recorded case in which the characteristic deposit of urate of soda has been found in the lungs, but if it were so, it is probable that it would produce an effect in some sense similar to what it does in the joints.

I may very properly approximate with the preceding those more frequent cases of true peptic asthma in which the gastric filaments of the pneumogastric nerve are irritated immediately by the ingesta, and this irritation is propagated reflexly to the pulmonary filaments and produces through them bronchial contractions (Salter). I have met with more than one such instance during the past winter. The following case is an illustration:

Case VII.—C. A. B., forty-three, single, waiter, was admitted to St. Luke's Hospital, November 21, 1888. Intermittent fever six years previously. Latterly has suffered a great deal from asthmatic attacks. *No nasal obstruction.* "Shortness of breath and cough, especially in the morning, is all patient complains of." Sibilant and sonorous râles in chest, tongue heavily coated with thick fur. Prescribed mixture rhei et soda, and in a few days gastritis was cured and asthma had nearly disappeared.

Case VIII.—J. P., forty-five years, clerk, came to New York Hospital on November 5, 1888. Complains of having asthma during past seven years. Has constriction of the chest most of the time, but is decidedly worse at night than during the day. Excessive beer-drinking seems to occasion asthma, and yet the condition of the stomach does not give the patient any concern. Asthma is also aggravated by cold and damp weather. Patient never consulted a physician, but usually has been taken care of by a druggist. Both nasal passages free, and feels well except for asthma. Asthmatic attacks as severe as formerly. Physical examination reveals in front and posteriorly over chest, sibilant and sonorous râles everywhere, heart normal, considerable area of dulness to left of vertebral column. This patient was advised to stop beer-drinking and given a carminative. His asthma improved. He was also ordered a blister of cantharides to be placed between the shoulders posteriorly over the dull area, 3½ in. by 4 in. This blister also proved to be very useful in alleviating the dyspnœic attack.

I am of opinion that this case was one of *peptic* and *bronchitic* asthma combined. No doubt the engorged peritracheal glands accounted for the area of dulness and were slightly diminished in size by the application of the blister—thus taking off pressure from the pneumogastric nerve trunk.

A case of the latter kind is the following:

Case IX.—H. D., thirteen years old, schoolboy, who came to the New York Hospital on October 8, 1888. He had been ill three months—suffering from cough, expectoration, dyspnœa, which became orthopnœa at night. When first seen a blister was applied between the shoulders. The blister did not raise the skin very much and was only of slight benefit.

Boy stated on October 18th that he had suffered from asthma since he was two years of age. He had been two years in New York; before he was in Ireland. When he was three months old he had a rash all over the body and on the head. He was told it was eczema. It lasted seven years. His asthma has improved somewhat since he came to the United States. Has taken cod-liver oil, quinine, Irish moss, etc., without much benefit, although at one time he suffered from chills and fever. During one month past his breathing at night has been very bad. *No nasal obstruction.* Cough and dyspnœa occur about 4 A. M., and last several hours. Damp and cold weather aggravate his condition.

Physical examination shows emphysema on both sides anteriorly. Sibilant and sonorous râles everywhere anteriorly, and in different regions posteriorly. On percussion a very considerable area of dulness is found to the right of the vertebral column, extending from the spine of the scapula to lower angle of it. Ordered fly blister, to be repeated several times at suitable intervals.

Oct. 26th.—Boy returned. Is feeling very well. Cough ceased immediately after application of the blister. Breathes perfectly. He was never relieved by any medicine as much as by the blister. Previously and subsequently this boy was given iodide of potassium, which also relieved him somewhat, but the blister had the most marked effect for good.

Lad continued well until December 22, 1888, when he had a recurrence of pain in chest, cough, and great oppression. He believes he caught cold, which precipitated his attack. Same treatment advised as previously.

This case, in my judgment, is one of those in which the asthma seems due to direct irritation of the pneumogastric nerve by enlarged bronchial glands. In these cases the iodides are of unquestionable benefit, and may be given advantageously not only during, but between, the dyspnœic attacks. Unfortunately, their use does not ward off their recurrence invariably, nor, indeed, always mitigate greatly their severity. Whenever there is much complicating chronic bronchitis, it is in these instances that I have most satisfaction from their use. If any plausible theory can be given of their utility, it would seem to be mainly in their power of promoting the reabsorption "of cellular exudates into inflamed tissues."[1]

[1] Journ. of Amer. Med. Assoc., May 25, 1889, p. 729.

Williams[1] favors the use of the iodide of potassium, and believes its beneficial action consists in the reduction of the enlarged glands through the influence of the iodine. The indications for prescribing this remedy are, according to him, (1) the absence of catarrh, (2) the well-marked presence of the neurotic element, (3) the detection of dulness along the right or left edge of the first portion of the sternum, or in both interscapular regions, showing enlargement of the bronchial glands. He combines arsenic at times with iodide of potassium with great advantage to the patient. The great value of iodide of potassium in the treatment of asthma has been confirmed within a few years by Lazarus and Lublinski,[2] the latter regarding it as a specific in this affection.

In several cases of extreme dyspnœa in which the lungs were apparently normal, and yet the patient could not support the recumbent posture, Andral has found enlarged bronchial glands pressing upon the pneumogastric and pleuric nerves. He therefore affirms that such a condition may be a frequent, if not a constant, cause of asthma. The observation is probably correct, although, according to Berkart, the inference is not so, since we sometimes find the pneumogastric nerves imbedded in large bronchial glands, and yet no dyspnœa has been produced.[3] We know, however, that enlargement of these glands is no infrequent accompaniment of affections of the lungs, either at their surface or deeper in their structure. In many cases this enlargement follows upon the catarrhal pneumonia of whooping-cough and measles, and[4] diminishes or increases according to the amount of, or obstacles to, the lymphatic current. Other changes than mere hypertrophy of these glands will doubtless depend greatly upon the constitutional tendencies of the individual. Although the enlargement of the bronchial glands diminishes with the subsidence of the inflammatory process which occasioned it, it seldom disappears entirely. It is especially in scrofulous patients where we find the greatest tendency to enlargement of these glands, and the slightest irritation may become an efficient cause of it. Cruveilhier[5] has found these enlarged glands repeatedly deep in the structure of apparently healthy lungs. The bronchi are often flattened by them. Now, then, if an inflammatory process of the air-tubes takes place, the latter may become greatly obstructed. This glandular enlargement was formerly supposed only to explain the intermittent dyspnœa of childhood. It is now known that it frequently occurs in adult life,

[5] Traité d'Anatomie pathologique, t. iv., 1862, p. 640.

and will thus account for many cases of asthma which otherwise are very obscure in their origin.[1]

With respect to children, Baréty[2] says that every time a child is attacked with dyspnœa resembling an asthmatic attack, we should not neglect to examine it carefully, and see if we can discover this form of adenopathy. Rilliet and Barthez, indeed, declare never to have observed nervous asthma in children. In all cases where they have observed continuous or intermittent dyspnœa they have found changes in the lungs, bronchi, or in the bronchial secretions.

The enlargement of the bronchial glands can rarely be discovered by percussion over the sternum, or between the scapula. But inasmuch as they serve to impede the entrance of air into the lungs, there is generally complete absence of respiratory sounds after cough as well as after manual compression of the chest. These symptoms are usually observed only on one side of the chest, whilst on the other side the different catarrhal rhonchi can be distinctly heard. Glandular enlargement in the neck, or in the supra-clavicular region on the side where the chest obstruction exists, are of great diagnostic importance.[3] The seeming integrity, however, of the thoracic organs is no sufficient reason why the cause of the asthma may not be found in the presence of glandular enlargement around the trachea or bronchi. This supposition is strengthened by the existence of bronchitis or emphysema.

For Rilliet and Barthez, the disease which offers the greatest resemblance with ganglionary asthma is intermittent, sibilant bronchitis. In the latter case, however, the sibilant râles are more acute and general, and in the interval between the attacks the general health is unaffected, and shows none of the signs of a grave or permanent alteration. Finally, the disease begins and ends like bronchitis.

Hyde Salter appears, also, to regard the swelling of the bronchial glands as a very frequent accompaniment of the bronchial inflammation to which eighty per cent. of all cases of asthma are traceable. Pressure on the vagi and their branches may result from this condition. To their effect on such glands is probably due the wonderful efficacy of iodides in asthma (*Amer. Journ. Med. Sci.*, 1888, vol. xcvi. p. 129).

In all cases of asthma of adult life it is important to examine the urine and see that it is healthy and free from albumin, so that we may not unwittingly have to do with an asthmatic attack which is merely a uræmic manifestation. In these cases, usually, œdema of the lungs is present. Of course, in view of our lately acquired knowledge, the larynx, and especially the nose, must be examined, to see that they are free from disease or from obstructive conditions.

I may now properly consider briefly my own experience of the importance of the nasal factor in the etiology of asthma. Since last autumn I have seen and treated about thirty cases of asthma due to different causes. Amongst these there were six in whom the asthma might be fairly ascribed to the existence of intra-nasal obstruction. Of these six cases, five were due to hypertrophy of the turbinated bodies in conjunction with more or less deviation and thickening of the nasal septum. The sixth case was one of mucous polyp. In all six cases operations on the nasal passages were undertaken. The nose was rendered pervious, and the patients experienced much comfort as a result of the operations. As regards the effect on the asthma, it was noted that in four cases the asthma was at least temporarily improved. In two cases there was no marked relief.

As will be noted in the histories previously reported in this paper, there were many cases in which asthma existed, and yet at no time was there any appreciable nasal obstruction. Further, I have seen a large number of cases, several of which I have operated upon successfully, in which there was pronounced nasal occlusion, and at no time had there been the slightest tendency to asthma. These facts, I regret to say, are not wholly in accordance with the statement of Dr. Bosworth, who, it will be remembered, presented a most interesting record of his experience at the meeting of this Association in Washington, last September. According to Bosworth:

"The existence of nasal disease was found to be present in every case in sufficient degree to warrant the conclusion that it exercised a powerful causative influence in the production of the asthmatic attacks."

The proof that this view is correct is shown, he says:

"in the fact that, of eighty cases, forty-six were cured, twenty-six were improved, three unimproved, and five unknown, and this entirely as the result of treatment of the nasal disorder. The inference," Dr. Bosworth adds, "can safely be drawn that, if the attack of asthma is cured by curing the nasal disorder, the asthma was caused by the nasal disorder."[1]

Dr. Shurly, I think, answered Dr. Bosworth's statement very successfully when he said that

"daily experience overwhelmingly shows a very large number of cases of intra-nasal disease in persons of neurotic habit, with a very small proportion of cases of associated asthma."

"We are going much too far," says Dr. A. H. Smith,[2] "when we seek to establish it as a rule that asthma is to be cured by operative procedures within the nose." As Dr. Daly affirms, it is unquestionably true "that there is

[1] N. Gueneau de Mussy, "Adenopathie Bronchique." Clinique Médicale, t. i, Paris, 1874, p. 569, et seq.
De l'Adenopathie Trachéo-bronchique. By A. Baréty. Paris, 1874.

[2] Loc. cit., p. 192.

a certain proportion of cases of asthma that can be cured by putting the naso-pharynx in a healthful condition."

And it is also true that some *cases of asthma* can be cured solely through the instrumentality of the cautery, the saw, the rongeur forceps, or the nasal trephine. As a case illustrative, however, of the negative effects of the latter treatment, I would report the following:

Case X.—P. C., laborer, sixty-one years old. During the past four years, or more, has suffered from cough, expectoration, dyspnœa, lumbar and chest pains. Patient cannot sleep in recumbent posture and has a paroxysmal attack each morning of cough and wheezing. On account of physicians' statements he attributes most of his symptoms to his nasal deformity—which was unsuccessfully operated on, the first time, two months ago, by a prominent specialist of New York, by means of the nasal saw; a portion of the septum was removed at that time. Some weeks later a second operation was performed on the same nasal passage with Jarvis' rongeur forceps. Since these operations patient can breathe more freely through the nose; still the asthmatic attacks are unimproved and patient is a great sufferer. On examination of the nasal passages, I find atrophic rhinitis, but very slight obstruction on either side. In questioning patient closely I find a distinct history of constitutional syphilis. I could not determine in this case what physical condition produced the asthmatic attacks, but was at least confident that the intra-nasal condition had little or nothing to do with it. Anti-syphilitic and symptomatic treatment were tried with little good result. Patient disappeared after two weeks' treatment.

Still it is true that the condition of the nasal passages demands a considerable share of attention in the judicious management of asthma. It is also obvious that the permeability of the nasal passages is essential in order that the function of respiration may be carried on properly, and that the respiratory surface may be protected, and especially against the evil effects of constant or intermittent mouth-breathing. In the latter case the lungs do not receive a proper supply of air, and this fact may be corroborated by listening to the chest of one who alternately breathes through the mouth and the nose. Moreover, the nose is a filtering apparatus, besides providing the proper amount of moisture to the inspired current of air, and if it be interfered with, the foreign bodies floating in the atmosphere, instead of being arrested on its lubricated vibrissæ, penetrate directly into the lungs and cause, necessarily, irritation and distress. Therefore, whenever an operation is required to render the nose permeable, and particularly so when there is a tendency to, or confirmed, asthma, it should not, if possible, be delayed or neglected.

Frequently, however, the nasal occlusion is due to a congestion of the pituitary membrane, which in these cases may be greatly diminished or wholly relieved by the medicinal agents which are employed for the purpose of restoring the freedom of the pulmonary circulation. Again, crusts, scabs, mucus, accumulate in the nasal passages at times, and promote an inflammatory process which can be temporarily relieved by a suitably formulated spray. I have known the hyper-sensitiveness of the pituitary membrane to be greatly diminished at times by repeated applications of carbolic acid with glycerine and vaseline. Indeed, in this way, I remember two cases of asthma of nasal origin, in which I effected a temporary cure.

To show the differences of opinion in regard to the intra-nasal treatment of asthma, and particularly by cauterization, I would add, that in the discussion following the reading of Lazarus' paper on this disease, at the Berlin Medical Society, "the general consensus of medical opinion seemed to be that the number of cases in which asthma was benefited by cauterizing the nasal mucous membrane on the turbinated bones, was extremely small." [1]

In summing up this subject I will quote, with some modifications, from a paper written by myself and read in 1886 before the New York Academy of Medicine.[2]

There are, without doubt, a great number and variety of affections, mainly neuroses, under the direct influence of morbid intra-nasal conditions; still, at the present time we should be careful not to exaggerate their importance, and whenever and wherever we find a neurosis of the respiratory organs immediately reach the conclusion that the nose occasions it. There is much truth in the observations of the past few years in regard to the predominating influence of a hyper-sensitive nose, but there is also a tendency to exaggeration in this regard, and we should be careful to exclude other efficient causes of *asthma* before admitting the nasal origin and instituting severe or prolonged treatment of this organ with a view to cure the *possible* secondary affection. The nose is naturally a sensitive organ, and many times I have produced epiphora, cough, spasmodic closure of the glottis moderate in amount, and slight dyspnœa, by the mere passage of instruments, or simple nasal examinations, when the result of my investigation was to show that no nasal trouble of importance existed. This is no new observation and I am conscious that all are familiar with it.

In reading the histories of clinical cases, we shall be disposed to take a one-sided view unless we secure the sobering influence which comes from extensive reading and larger experience. The only way, I believe, in which we can avoid error at present in

[1] Annual of the Universal Med. Sc., 1888.

[2] Respiratory Neuroses of Nasal Origin, N. Y. Med. Rec., p. 119, 1886.

this seductive question, is to search carefully for other cause, or causes, of asthma, and when none are discovered, then, and then only, we should admit the nasal origin of the neurosis, and institute treatment in accordance with this conviction. I agree entirely with Lublinski, who says: "If there is really a nasal affection, it should be treated according to its character, and not on any far-fetched theory of its etiological importance" (*Med. Rec.*, May 27, 1887). This being my opinion, I must reluctantly separate myself from any such radical position as that upheld by my eminent colleague, Dr. F. H. Bosworth, of New York, who writes that he has seen no case in which intra-nasal disease was not found as a predisposing cause of asthma. And again, to quote him textually, he has "never known a case of asthma to occur in other than an obstructive lesion of the nose or upper air-passages."[1]

Another form of asthma, which, to me, is rare and interesting, was recently seen by me at my office.

The history is as follows:

Case XI.—J. K., forty-nine years old, married, Swiss, laboring man, has always suffered from pains in the head and oppression on chest. Patient has noticed when pain in the head disappears his feeling of oppression in the chest becomes worse. This oppression is accompanied with occasional dry cough. The suffering from the oppression is most severe during the night. During the day, as a rule, he does not suffer much. Patient is awakened frequently during the night with attacks of difficult breathing. He is often constipated, and has nausea and vomiting, but the cephalalgia is the symptom which is most distressing.

Physical examination shows a large head with prominent, square forehead. Such a conformation of the cranium existed as we find in children suffering from moderate hydrocephalus with rickets. Patient remarked that he was said to have had a remarkably large head when a boy, and he remembers distinctly having had for many years as a youth profuse cranial sweating. His legs are moderately straight, but the general appearance of the man is delicate and slight. The lungs show probable fibroid induration, yet patient states that he has not coughed during the past winter. Often he awakes with difficulty of breathing at night when he has no cough at all. Dulness over right interscapular region.

Diagnosis was: Old rickets, with probable hydrocephalus leading to cerebral irritation, which condition is the cause of asthmatic attacks in a patient made additionally susceptible by the existence of a fibroid lung. The gastric catarrh and paresis of the lower bowel appeared to me of the nature of concomitant symptoms of the preceding conditions. Patient is coughing somewhat to-day, without expectoration. He is suffering from his head, and has notable difficulty of breathing. Upon close questioning anew, again patient insists that since childhood he has always found that his head pain originated the asthmatic seizures, although when the head became decidedly better the asthmatic attack grew rapidly more *intense and distressing*. Whilst the patient was in my office I administered a considerable dose of bromo-caffeine, and within fifteen minutes after taking it his pain in head, difficulty in breathing, and cough were all almost entirely relieved. I ordered him to continue bromo-caffeine at proper intervals during twenty-four hours. Next day patient returned to my office and said he was decidedly better in every way—head less painful, no difficulty of breathing, and scarcely any cough. Thinking the patient needed building up, and that his bowels required attention, I ordered syr. hypophosph. comp. and a vegetable cathartic pill.

This case approximates somewhat, I believe, those described by Paulet[1] as epileptic asthma,

> "who believes this form merits the name of epileptic neurosis of the gastro-pulmonary filaments of the vagus nerve. It is characterized by varying paroxysms succeeded by health. In many instances these attacks are preceded by *pain in the head* comparable to an epileptic aura. They come on during the day, and vomiting is a frequent symptom. It is a peculiarity of the affection that it is not improved by the routine treatment of asthma, but is successfully combated by that of epilepsy."[2]

This guides to a new line of treatment which has marvellous efficacy—*i.e.*, the use according to Paulet of large doses of bromide of potash combined with picrotoxine and soda.

This author states that the paroxysms were almost entirely suppressed at one stroke; but a single attack occurred at the end of ten days. Certainly my isolated case bears out the possibility of such a result.

In conclusion, I would say that I have not alluded to those very frequent cases of asthma—in fact, we may call them the usual ones—which are dependent upon old bronchial catarrh, accompanied by emphysema and more or less chronic changes in the cellular structure of the lungs. I have abstained from this because my paper is already unduly long, and because this interesting topic may be reserved for ulterior consideration.

THE PREVENTION AND ARREST OF PUERPERAL MASTITIS AND ABSCESS BY METHODICAL FRICTIONS.[3]

By EUGENE F. CORDELL, M.D.,
of Baltimore

As might be inferred, an organ which is subject to such alterations of complete dormancy and unintermitting function, and to such frequent traumatism, as the female mamma, is exceedingly liable to disorder and disease, and especially to disturbance and

[1] Journal de Médecine de Paris, Feb. 19, 1888.

[2] Annual of the Universal Med. Sc., vol. i., A. 79, 1889.

[3] Read before the Clinical Society of Maryland, May 17, 1889.

arrest of function. Whilst there is not complete agreement as to the causes and mode of origin of puerperal mastitis, most writers assign the greatest consequence to those circumstances which—as affections of the nipple—may be supposed to interfere with the due discharge of the milk. Fissures and ulcers of the nipple are considered by far the most active etiological factors (Playfair, Lusk, Spiegelberg, Parvin, Charpentier, and Gallabin), whilst cold, pressure, injuries, depressing emotions, general septic infection, the breast pump, imperfect development of the nipples, etc., play an altogether secondary rôle.

It is not difficult to comprehend how the group of affections first named may interfere with excretion, and, secondarily, also with secretion. They are exceedingly painful, and the attempt at nursing being usually persisted in, they not only have no chance to heal, but often become greatly aggravated by the constant traction due to suckling. The intense suffering to which the mother is thus subjected, no matter how great her maternal instinct and resolution, inevitably leads her to avoid, as much as possible, the painful ordeal. In consequence, the milk accumulates in the tubes, forms clots, and the flow ceases for the time. This is not all: it also undergoes the lactic acid fermentation, and, compressing the bloodvessels, leads to engorgement and hyperæmia, and their natural sequence—arrest of secretion. Paresis of the muscular fibres entering into the walls of the milk-ducts must play some part in the disorder here, as in other hollow organs of the body which are subjected to undue distention from accumulation of their contents.

This is not all that we can say of the etiology of these mammary troubles. Analogy and late researches have indicated that there are silent and invisible excavators at work, and that it is by means of the microscope that the etiological problem must be solved. Of the latest standard authors who have been accessible to me, but one as yet alludes to the direct introduction of septic matter. "In almost all cases," says Parvin (*Obstetrics*), "a lymphangitis arises from the introduction of septic matter through a wound on the nipple, beginning by a crack, fissure, erysipelas, etc." The following investigations bearing upon the bacteriological aspect of the question are upon record: Bumm (*Arch. f. Gyn.*, xxvii. p. 460, and *Amer. Journ. Med. Sci.*, 1886) found two kinds of cocci in mammary abscess, the "staphylococcus pyogenes aureus" and the "streptococcus pyogenes." The former grew readily upon almost any nutritive soil, but the latter was not so easy to cultivate, and formed smaller and more delicate colonies. Of fifteen cases in which the cocci were discovered, the staphylococcus was present in eleven and the streptococcus in four. He believes that these organisms directly induce phlegmonous inflammation by their growth and proliferation, the abscess beginning in the case of the staphylococcus with deep-seated inflammation spreading outwardly to the surface, whilst that due to the streptococcus usually begins with superficial inflammation extending to the deeper parts. The starting-point of the infection is usually an abrasion of the cuticle, although it occasionally travels up the milk-ducts. He also found similar organisms in milk just drawn, but not in all specimens from the same breast. He concludes that there is danger in allowing the milk to stagnate in the mammary glands.

Olshausen (*Deutsche med. Wochenschrift*, April 5, 1888, and last edition of Schröder, *Amer. Journ. of the Med. Sci.*, 1888) confirms entirely the statements of Bumm, and adds that the decomposition and acid fermentation of milk are produced by bacteria; and, on the other hand, the development and extension of the latter are favored by the former. Escherich (as quoted by Olshausen) appears to have made observations of a similar purport; and, finally, E. Cohn (*Zeitschr. f. Geb. und Gyn.*, xi., 2; *Amer. Journ. Obstet.*, 1886) found the same pyogenic cocci in seven out of eight cases, leading him to conclude that mastitis does not result from milk retention in the absence of the specific microörganisms. These investigations seem to leave but little doubt that the true solution of this question has at last been found.

When we come to the prevention and treatment of mammary inflammation, we find still greater disagreement. Some, as Mundé (*Cazeaux and Tarnier's Obstet.*, 8th Amer. Ed., Philada., 1889) and Harris (quoted by Parvin, *Obstetrics*, Philada., 1886), rely upon compression and rest; "rest," says Harris, "from passive motion, rest from secretion, rest from pain." "*No rubbing or manipulation* of the breast is allowed under *any* circumstances," says the former; whilst the latter interdicts nursing, friction, pumping, fomentations, and all local means except those designed to secure rest.

All are not of this opinion with reference to the harmful effects of friction. Playfair, for instance (4th Amer. Ed.), recommends "gentle hand friction" to remove "engorgement of ducts." Lusk (*Midwifery*, New York, 1887) allows that "partial relief to excessive fulness of the milk ducts" may be secured by mammary expression; and Barnes (*Med. and Surg. Obstetrics*, Philada., 1885) says that frictions during the engorgement which precedes inflammation are useful to promote secretion and help retarded milk along the ducts, but cautions that they should be gentle and light, for if injudicious they may become the cause of inflammation.

Notwithstanding the objections made by such high authorities as I have cited, the method of treatment by frictions seems to me to commend itself not only upon rational grounds, but also by the results of experience. The accessibility of the glands and the

anatomical arrangement of the ducts, converging, as they do, from the periphery toward a common centre, and from smaller tubes to larger, enables us to employ pressure with the very best effect. By softening the clots and propelling onward the stagnant and fermenting milk we relieve the pressure, irritation, and pain, and facilitate the subsequent excretion of the retained material. Furthermore, we propel this material in a direction by which its removal alone can be effected. Again, by getting rid of it, either by the natural method of suckling, or by artificial means, we empty the overloaded ducts, we remove pressure upon the bloodvessels and nerves, diminish vascular engorgement, and undoubtedly favor the proper secreting functions of the organ. And, finally, if it be true that microorganisms are at the bottom of the morbid process, what other means are left open to us for eliminating or getting rid of these but by thus depleting the organ by channels which nature has provided?

Clinical experience, the ultimate test of all therapeutic measures, offers still stronger proofs of the value of this method. Many and many is the time I have seen a swollen, engorged, and exquisitely tender breast restored to its natural condition by a few gentle rubbings. I have seen the same result ensue when a violent chill, intense fever, profuse sweating, and an angry-looking discoloration seemed to point to inevitable abscess. So that my confidence in my ability to check the commencing inflammation is now so great that I feel perfectly certain of a favorable result; and since I began the use of frictions, some sixteen or eighteen years ago, I have not seen a single case of parenchymatous abscess, and only one small subcutaneous collection of pus, whilst during previous years I can recall several very painful and protracted cases, involving great suffering and helplessness, demanding deep incisions, and sometimes rendering a breast useless ever after.

There is such almost unvarying uniformity about cases that I will only cite the two following as typical of my clinical experience:

S. C., multipara, nursing an eight-months child. For two days the baby has had a bad cold and has not been able to take the breast. Consequently the milk has ceased flowing and the breast has become sore. That afternoon she had a severe chill. At 8 P.M. she was still chilly, temperature, 103°; pulse, 108. Breast exceedingly tender and the seat of severe pains extending down the left side with "cramps." Also severe head and back ache. I ordered strict confinement to bed, and support by means of a folded handkerchief; gave a dose of quinine and morphia and directed the breast to be gently rubbed every six hours, from the circumference to the nipple, with warm oil and laudanum, equal parts. The next day I was surprised to find her attending to her household duties, going up and down stairs, her fever gone entirely and the pain and tenderness much diminished. She continued the rubbings a short time longer, but had no further need of my services.

A. H., nursing multipara, aged thirty-three. Two days after experiencing a severe chill, her left breast was exquisitely tender and painful and greatly swollen. There was a red and angry-looking spot, some one and a half inches in circumference, on the upper and inner surface of the gland. Warm oil and laudanum frictions were ordered and faithfully applied and she took a dose of salts. After two days the breast was softer, less heavy and painful. She had no further chill, and in a day or two was as well as usual.

Whilst I rely upon the frictions to restore the crippled organ to its full integrity, I am not willing to dispense with such additional measures as may seem to be useful in aiding in this restoration or in alleviating their discomfort. Hence, I enjoin complete rest, and support by means of a handkerchief tied over the opposite shoulder. A dose of salts is rationally indicated, and anodynes may be demanded. The value of quinine, aconite, belladonna, iodine, and other agents, recommended by many, is conjectural. It is important, for reasons which I have stated, that the milk should be drawn from the ducts, and hence nursing should be continued if possible, as the natural effort of sucking is the most effectual way of drawing the milk. In case of fissure or ulcer of the nipple, it may be rendered less painful by the use of a "Phœnix" nipple-shield.

Circumstances may arise rendering it necessary to have the milk drawn by the husband or nurse, or by a breast pump, although I have had but little satisfaction from the use of the latter. I do not share in the opinion of Jacobus, of New York (*American Journal of Obstetrics*, 1883), that it is about as rational to attempt to draw out the contents of a boil by suction as it is to extract those of an inflamed breast.

Of course, affections of the nipple demand appropriate applications and the utmost cleanliness, and some disinfectant, as borax and sugar, equal parts, should be applied to the infant's mouth before nursing.

In this communication, I do not wish to be understood as asserting that the method which I have advocated, and which is not at all original with me, is the only one by which mammary inflammation and abscess may be prevented or arrested. But, I do believe, that it is one by which those results may be attained with a very great degree of certainty, and even allowing that other things are equal, it strongly recommends itself by its simplicity and ease of application. Acting, therefore, upon the suggestion of one of the most eminent of English clinicians—Dr. Thomas King Chambers—I do not

consider it necessary to retain in my medical armory, to be used for that same purpose, the less efficient measures which it has superseded.

2111 MARYLAND AVE., BALTIMORE.

REMARKS ON THE TREATMENT OF PULMONARY PHTHISIS.[1]

BY J. C. WILSON, M.D.,
OF PHILADELPHIA,
LECTURER ON PHYSICAL DIAGNOSIS, JEFFERSON MEDICAL COLLEGE, ETC.

UNTIL the present decade, no theory adequate to explain the facts in regard to the origin and nature of the tuberculous diseases, and especially of pulmonary phthisis, had been advanced. One hypothesis after another had been advocated only to be abandoned, leaving a heritage of erroneous views and misleading phrases to encumber the general stock of information. Pathologists, in their eagerness to cope with the most grievous scourge of modern civilized life, generalized upon insufficient data. The progress of knowledge in regard to this group of diseases was, therefore, slow and halting. It consisted chiefly in the accumulation of facts, among which there can be found neither coherence nor relation. Many of these facts, collected with untold toil, are to-day without significance or value, except to overthrow the views for the support of which they were gathered. When all was said, it seemed as though the progress from the time of Laennec to 1882 was scarcely worth mentioning. To-day it appears to many of us to have been no progress at all.

Koch's discovery of the tubercle bacillus, and his demonstration of its causal relation to the tuberculous diseases, mark an epoch in medical history. Since that time scientific research has taken the place of ingenious surmise, and the evolution of a theory constantly supported by new and interdependent facts has gradually illuminated the darkness that overspread the subject of tuberculosis. It is true that there are yet obscure corners and unsolved problems. The present is a period of transition. But the confusion of the present has this advantage over the chaos of the past: there is a hopeful prospect that out of it will evolve order.

Let us regard pulmonary consumption in all its forms as a type of the tuberculous diseases.

This much may be safely predicated:

Pulmonary consumption is an infectious disease, due to the implantation and development of the tubercle bacillus in the lungs of a susceptible individual.

It is of advantage to present this proposition in its simplest form. It follows that the tuberculous diseases of other organs are infections, likewise due to the access and development of the tubercle bacillus. The pathogenic unity of the tuberculous diseases and the primary localization of the process are obvious deductions. The overflow of local collections of tubercle bacilli, or of matters laden with them, by way of continuous surfaces or perforating lesions, explains the extension or the generalization of the process; thus, for example, from one lobule to another, or to another lobe, or to the opposite lung, or to the larynx, or upon deglutition to the intestine, or, again, by the erosion of the capsule of a lymphatic gland, to a bronchus, or into a vein, with the production of acute general tuberculosis. But acute general tuberculosis is a rapidly fatal disease, presenting strong points of resemblance to the specific fevers, especially to enteric fever. Let us confine our attention to the local lung disease. If it be local, how are we to account for the constitutional symptoms?

The results of recent researches in the field of the chemistry of the infections render it in the highest degree probable that many of the general symptoms of these diseases are not directly, but only indirectly, due to the bacteria which constitute the infecting principle. Toxic substances—ptomaines—are continuously evolved during the period of the development of the pathogenic bacteria in the organism. These principles, being soluble in the circulating blood, occasion constitutional phenomena analogous to those caused by certain alkaloidal poisons. Several of these substances have been isolated.

The grave constitutional symptoms which are sometimes associated with circumscribed lesions, the general improvement frequently observed during periods of quiescence on the part of the local process, the disappearance of symptoms in cases where the local process becomes obsolescent, the prolonged fair health which is occasionally seen in individuals with extensive but distinctly encapsuled cavities, all lend support to the view that in pulmonary consumption likewise, not the bacillus itself, but ptomaines which it produces, are the cause of the malnutrition, asthenia, fever, sweating, and other general symptoms of the active disease. That these ptomaines are among the products of the disintegration of tissue elements from which the bacteria derive pabulum is obvious. To arrest such tissue-disintegration would mean, on the one hand, to prevent the formation of ptomaines; on the other, to deprive the parasite of the pabulum necessary to its growth.

The destruction of pathogenic bacteria outside the body, or the prevention of their access, constitutes prophylaxis. Where measures of this kind are efficient, the question of individual susceptibility or predisposition becomes of minor importance. When such measures are inadequate, the prophylaxis must include efforts to render the individual insusceptible,

[1] Read before the American Climatological Association, June 26, 1889.

efforts which have been fully realized by vaccination in smallpox.

In broad, general terms, disinfection includes two processes, which, however, are not in all instances distinctly separated, but which often overlap. These are,

1. The destruction of germs.
2. The sterilization of organic substances.

The first is a germicide process; the second, an antiseptic process. Measures of disinfection employed in the sick-room and in the treatment of the excreta of the sick are germicide. Here the object is the destruction of bacteria. The processes by which meats are preserved, as by smoking, salting, and the like, and the means taken to preserve pathological specimens and cadavera for anatomical use, are antiseptic. Here the purpose is, not to act directly upon the bacteria which may produce destructive changes, but to act upon substances liable to those changes in such a manner as to render them infertile for the growth of the bacteria.

Efforts have been made to utilize both these methods in the curative treatment of disease. In theory one or the other or both of them are available in the treatment of tuberculosis, a local infection gradually extending by the implication and destruction of new areas of tissue, the elements of which are necessary to the growth and development of the bacillus. Superficial tuberculosis is, under certain circumstances, amenable to germicide treatment in the simplest form. Thus the enucleation of superficial tuberculous lymphatic glands and the effectual scraping and disinfection of the surrounding tissues, now constitute an accepted and efficient treatment. The medical history of the last seven years teems with the records of unsuccessful efforts to utilize various germicide methods in the treatment of pulmonary consumption. The apparent early successes of several of these methods are to be explained, partly by the enthusiasm of those who have advocated them from the beginning, and partly by the fact that consumptive patients, especially when congregated together in hospitals, are liable to present misleading evidences of improvement for a short time after the employment of methods of treatment at once novel and having a specious appearance of being scientific. Their failure is due to the fact that the tubercle bacillus is more resistant to germicide substances than the tissues which constitute its natural habitat.

Even in the case of exposed tuberculous ulcers or of pulmonary cavities so situated as to be accessible to germicide drugs, either by inhalation or by direct injection through the chest wall, the bacilli in the surface discharges, or in the accessible curdy necrotic material collected upon the cavity walls, are no longer active in causing the tuberculous process. They are simply admixed with material ready to be thrown off, and are dangerous only in so far as they are liable, by transposition to unaffected tissues, to light up new local processes. The bacilli which are active are deeply imbedded in tissues inaccessible to any germicide which does not, at the same time, involve in destruction the parasite and the structures which constitute its host.

One germicide method only, and that the latest, has not yet been shown to be unsuccessful. It is the method of Weigert, and consists in the prolonged inhalation of superheated air. Whether or not the tissues of the human lung can preserve their integrity, when exposed to air of a temperature ranging from 212° F. to 480° F. sufficiently long to destroy the tubercle bacilli imbedded in them, remains to be demonstrated.

In the antiseptic plan we have a method of treatment likewise based upon the pathogenic rôle of the bacilli. This plan has for its object not to directly destroy the bacillus, but to augment the powers of resistance of the structures which it assails. If the tissue elements can be made to withstand the disintegrating action of the parasite, then the chemical changes by which are elaborated, on the one hand, the nutritive material needed for its growth, and, on the other, the poisons which cause the general symptoms of the disease, would be prevented. To this plan must be referred those methods of treatment which have been generally recognized as beneficial, including measures of hygiene, dietetics, with hyper-alimentation and the administration of fats, pulmonary gymnastics, and climate, the object held constantly in view being such an improvement in the general condition of the patient as to retard or bring wholly to an end the destructive processes in the lungs.

Among medicines, the utility of which has been long and generally recognized, are the preparations of iodine; the preparations of mercury; arsenic; the phenols, especially carbolic acid and creasote.

The members of this group have one striking peculiarity in common, namely, that they are powerful antiseptics. With the exception of the phenols, they belong to the group of medicines known as alteratives; and the question suggests itself, in this connection, as to whether or not their so-called alterative influence is not, to some extent at least, due to an influence which, in long-continued moderate doses, they exert upon the tissue elements of the body in such a way as to increase the powers of resistance of the latter to disintegrating morbific agencies.

Clinical researches in this direction are not without promise. Alteratives of this kind have hitherto been employed simply upon very vague opinions regarding their general influence upon nutrition. If they can be shown to exert a special influence upon nutrition antagonistic to the action of pathogenic bacteria, not only will their usefulness be much

increased, but clinical problems relating to the mode of administration, dosage, and effects, will at once engage the attention of practical therapeutists.

The existing methods of treatment are unsatisfactory. Germicide methods have proved utterly futile. The suggestion of an antisepsis that will increase the powers of resistance in the living tissues opens up a field worthy of systematic cultivation. Two things are especially needed: first, the earliest possible recognition of the local lesions of pulmonary consumption; second, the earliest possible employment of the combined means which have shown themselves in the hands, not of one, but of many practitioners to be useful. These are improved hygiene, dietetics, climate, respiratory gymnastics, and the use of alteratives.

The universal experience of those engaged in making large numbers of post-mortem examinations shows a frequency of obsolescent tuberculous lesions in the lungs, such as warrants a large degree of hope in the energetic treatment of the disease in the stage of primary infection. The conventional disregard of the earliest symptoms, both on the part of patients and physicians, is unfortunate. Far better for the doctor to tell the patient his worst fears at once, and institute the treatment at a time when the evidences of tuberculous infection are still doubtful, than to temporize until large areas of pulmonary tissue are implicated, and the growing parasite has become a fruitful source of new infection, both within and outside of the body of the patient.

SUPRAPUBIC CYSTOTOMY IN A CASE OF ENLARGED PROSTATE AND FALSE PASSAGE.

By M. STAMM, M.D.,
of Fremont, Ohio.

At the last meeting of German surgeons in Berlin, in speaking of the treatment of enlarged prostate, Fürstenheim mentioned a case occurring in the practice of Israel, which the latter surgeon presented to the Surgical Society of Berlin some time ago. This patient was a female and for some reason Israel punctured the bladder above the symphysis. This puncture resulted into a fistula through which the patient could empty her bladder by means of a catheter without any pain. Fürstenheim reasons from this case that a similar method, preferably an incision, might be adopted in cases of hypertrophy of the prostate where patients have great difficulty in introducing a catheter. Most surgeons seem to agree that it is not so much the enlarged prostate as the catarrhal condition of the bladder, which causes the real danger in such cases. In my opinion a suprapubic cystotomy would greatly reduce this danger and would admit of a thorough examination and irrigation, both of which cannot so well be accomplished by any other method.

The following case furnishes a result which Fürstenheim would expect from such a procedure.

C. C., of Kansas, Ohio, about seventy-five years of age, had been suffering from prostatic hypertrophy for several years and had to draw his urine by means of a silver catheter for a long time. On April 6, 1888, as he was not able to empty his bladder as before, he came to my office. Not finding me at home, and being in great agony, he went to some other physician, who, after protracted efforts, made a false passage, but did not succeed in getting any urine. In the morning of April 9th I was called in consultation with Dr. Jump, of Kansas, and found the bladder distended up to the umbilicus; scrotum and perineum were of a dark purple color, some spots showing already signs of gangrene. Every attempt to get into the bladder through the urethra was frustrated. Prostate examined per rectum seemed very much enlarged. As parts along the urethra were very much bruised and mortification appeared imminent, I decided to make a suprapubic incision. After having opened the bladder a very large quantity of urine mixed with some slime was emptied. The middle lobe of the prostate gland was of the size of an egg and acted as a valve upon the urethra, a considerable pocket of the bladder was also formed by it. The bladder was then stitched to the wound and a strip of iodoform gauze left in for drainage and as a disinfectant.

Patient rallied well from the operation, but his fever kept up for about one week until the bruised parts had sloughed off. About three weeks after the operation the opening had contracted so that a large-sized catheter could easily be introduced. I had a silver canula made after the shape of a tracheotomy tube, but patient found he could get along better without such a contrivance. He can now retain his urine for several hours, empties his bladder with a soft catheter through the fistula about six times a day and is better satisfied with his present condition than he had been for several years before the operation.

MEDICAL PROGRESS.

Chloralamid, a New Hypnotic.—While, at a first glance, it may seem quite superfluous to add another to the already long list of hypnotics, closer observation will show that this is not the case. Whilst, on the one hand, many lack promptness in action, on the other hand, many of those whose hypnotic action is rapid are accompanied by such grave symptoms that their use can only be resorted to with extreme caution. The actual number of reliable, efficient, and, at the same time, safe hypnotics, is very small. The introduction of a new one, which promises to combine the above-named desirable properties, should be joyfully welcomed rather than regarded as a superfluous addition.

Chloramid, as introduced by v. Mehring, is a product of anhydrate of chloral (CCl_3CHO) and formamid ($CHONH_2$) and therefore has the formula $CCl_3CH\begin{smallmatrix}OH\\NHCHO\end{smallmatrix}$. It is

a colorless crystaline substance, soluble in nine parts of water and in one and a half parts of alcohol (96 per cent.). Its taste is mild, slightly bitter, but not biting. The watery solution keeps well.

Dr. Ed. Reichmann reports quite a large number of cases in which he has used the drug; the dose given being almost invariably thirty grains. The hypnotic action was in all cases most prompt; sleep ensuing within an hour after the dose had been taken. No unpleasant accompanying or after effects were noted. The patients awoke the next morning refreshed and feeling as usual. Sphygmographic tracings were taken during the influence of the drug, but revealed nothing but normal heart action. Reichmann concludes that chloramid is a safe and rapidly acting hypnotic, when given in doses of thirty to forty-five grains. Sleep ensues in half to three-quarters of an hour, seldom later. Its rapidity of action is, therefore, equal to that of sulfonal.

The absence of all unpleasant accompanying or after symptoms, as well as the absence of any circulatory disturbances, will probably bring the drug into extensive use and make for it a place among the principal hypnotics.

A New Tubercle Bacillus.—We read in the *Gazette hebd. de Méd et de Chir.*, that Dr. J. Courmont claims to have found a new tubercle bacillus in a pleural lesion of an ox affected with tuberculosis. Cultures of this new bacillus, which is quite different in appearance from the tubercle bacillus of Koch, produced tuberculosis in from fifteen to twenty-five days when injected into rabbits. In the rabbits thus infected he found large quanties of the new bacillus, but Koch's tubercle bacillus was absent in every case. The new microbe was also found in the blood of the animals infected. It thrives well at a temperature of 97° F.

Experimental Study of Brown-Sequard's Theory.—An interesting article on the efficacy of Brown-Séquard's hypodermatic fluid appears in the *Medical Record* of August 24th, from the pen of Dr. Henry P. Loomis. Besides reporting in detail ten cases in which the liquid was used, Dr. Loomis has investigated critically the merits of the preparation. Careful antiseptic precautions were observed in all the experiments.

Dr. Loomis, whilst regretting that so much has been engrafted upon Brown-Séquard's theory that has no shadow of foundation in any contention of the originator, in which there is nothing to support the accusation that he claims to have discovered a source of perpetual youth, but rather a flat denial of any such contention.

The ten cases reported by Dr. Loomis are divided into two classes, the first including only such as were patients in the Bellevue Hospital, and who had no knowledge or suspicion of the character of the liquid; the second class embraces, with one exception, private cases. All were men of intelligence and education, and were familiar with the theory and method of treatment.

Dr. Loomis summarizes his observations as follows:

I. (*a*) He sees no reason to anticipate danger of septicæmia from the use of the fluid prepared under proper antiseptic precautions, provided the material used be absolutely fresh and free from all trace of disease. His attention was called to the necessity for the closest scrutiny in this last particular, by having discovered, in specimens taken from an apparently healthy ram, a solitary tubercle, in which were demonstrated tubercle bacilli. In none of the cases has he seen any bad results, and only in a few has there been a moderate amount of pain at the point of injection, lasting from six to eight hours.

(*b*) He can explain the singular nervous affection apparent in certain of the cases only on the theory that upon the nerve-centres the mixture exerts some powerful but as yet unexplained influence, which, even if its use be eventually proved beneficial in some cases, must render its employment in others a matter of caution. It is far from safe to say and proceed upon the belief that "if it does no good, it can do no harm."

II. (*a*) He seems to see in almost all the cases of *old men* subjected to the experiment an increase in strength and vitality which certainly persists for several days. He has noticed nothing in the least resembling the secondary depression which so commonly follows the use of ordinary stimulants.

(*b*) When used in cases of actual disease no modification of pathological conditions or processes has been recognizable.

He, therefore, concludes:

1. That the injection of this testicular mixture does, as claimed, produce "nutritive modification" in the tissues of elderly men, due probably to the stimulation of the nerve-centres.

2. As far as his own experiments are concerned, sufficient time has not yet elapsed to justify an affirmation or denial of the correctness of Dr. Brown-Séquard's second conclusion.

3. There is in the theory sufficient ground for further experimentation.

Bromoform in Whooping-cough.—The number of remedies used and recommended in whooping-cough is very large; still new ones are continually cropping up. This proves that among existing drugs there has been no perfectly satisfactory remedy for this disease. Carbolic acid, for inhalation in the shape of vapor, and quinine given internally, are therapeutic methods in which the greatest confidence has been placed. Lately that hard-worked drug, antipyrin, was also called upon to act specifically in this disease. After trying vainly to fulfil the requirements imposed upon it, antipyrin is quietly withdrawing from the field. Chloroform in small doses, given internally, has also given considerable satisfaction, and it was this fact that called Dr. Stepp's attention to the possible utility of bromoform in whooping-cough.

Bromoform is a clear, colorless fluid, having a peculiar, although not an unpleasant, odor. Its chemical composition is $CHBr_3$, specific weight 2.9—therefore, is twice as heavy as chloroform. It is easily soluble in alcohol, but very slightly so in water, seven or eight drops dissolving in four fluidounces of water only after continual shaking. If well corked, bromoform water will keep indefinitely. Pure bromoform has a sweet taste, and does not burn the mucous membrane of the mouth, as chloroform. When evaporated over a lamp it gives off strong bromic fumes, which are intensely irritating to the mucous membranes of the conjunctiva, throat, and nose. It seems to be more volatile than chloroform. When given internally no unpleasant accompanying symptoms were observed, either in adults

or children; Stepp maintains that the drug is not poisonous. No influence either upon the pulse or temperature was noted. The dose *pro die* for children was five to twenty drops of bromoform in four to four and one-half ounces of liquid. Owing to its poor solubility in water, the following formula is advised:

℞.—Bromoform	. . .	gtt. x.
Alcohol	. . . .	f℥j to f℥jss.
Water	. . . .	f℥jv.
Syrup	. . . .	f℥iij. —M.

This may be given in teaspoonful doses every one or two hours, as necessary. Stepp, in the *Deutsche med. Wochenschr.* for August 1st, reports nearly seventy cases of whooping-cough which he has treated successfully with this remedy. Dr. Goldschmidt cured a severe case which was complicated by pneumonia, in two weeks by its use.

A remarkable feature of the treatment is that no catarrhal symptoms are present during its use, and in cases where such had existed, they speedily disappeared. Stepp says that experience has taught him that the size of the dose should be in direct proportion to the age of the patient and to the intensity of the attack. He shortly intends to publish an exhaustive dissertation on the subject. The ease of administration, and absence of unpleasant accompanying symptoms, aside from the beneficial action which is claimed for it, surely warrant its trial by the profession.

Prophylactic Hair-wash.—The following hair-wash, given in the *Therapeutische Monatsheft* for July, 1889, is said to keep the scalp cool and the hair dry and free from oil, also to prevent dandruff, besides being a most agreeable toilet preparation:

℞.—Spirit of ether	. .	f℥jss
Tincture of benzoin	. .	f℥jss to f℥ij
Vaniline	. . . .	♏j
Heliotropine	. . .	♏iij
Geranium oil	. . .	gtt. j.—M.

Sig. For hair-wash. Keep well corked and do not expose to flame, as the mixture is highly inflammable.

The late Typhoid Epidemic in Berlin.—DR. FÜRBRINGER, the Director of the City Hospital, Friedrichshain, lately gave some particulars relating to the late epidemic of typhoid fever before the medical society. The epidemic began in the middle of January, and lasted to the end of March. During this period 155 typhoid cases were admitted into hospital, four-fifths of the average yearly admissions. Sixteen of these died, 10.3 per cent., the average mortality being 17.3 per cent. Of men, 12 per cent. died, of women 8 per cent., and of the children 15.5 per cent. The higher mortality among the males was attributable to the drinking habits of the class of population affected. The total cases officially notified amounted to 510. These radiated from three distinct centres; the soil or drinking-water theory afforded no explanation of the outbreak, as the parts most affected were included in the sewage system, and the drinking-water came from the ordinary water supply or from springs. In the hospital, four sisters and two attendants were attacked; all recovered. There was no other case of infection, although on account of great overcrowding in the hospital complete isolation was impossible. From this it followed that as soon as the feces were quickly and thoroughly disinfected the disease was not transmitted from one person to another. This took place in the bed-pan in a five per cent. solution of carbolic acid, and the bed linen was placed immediately on its removal into a solution of sublimate, and in this state passed into the wash. Continued washing of infected linen was a source of danger, either from the infection through a wound on the finger, or from the inhalation of dried desiccated discharges, or because the exhausted body afforded less resistance to the entrance of germs. Neither calomel nor naphthaline was used, the diet was stimulating or strengthening, and in individual cases a mild bath treatment was adopted. The average stay in hospital was 34.6 days. Three cases of perforation of intestine were cured.

DR. GOLTDAMMER, of the Bethanien Hospital, considered the last epidemic to be the severest they had had for fifteen years. It was not dangerous for other patients to have typhoid fever amongst them. Of 72 cases 14 died, equal to 20 per cent., whilst in former years the mortality had been 9 per cent. Death resulted generally from grave complications, 4 died of paralysis of the heart and lungs, 4 of perforation of the bowel, 3 of hemorrhage, 1 from each of the following, viz., pyæmia, diphtheria, œdema of the glottis, empyema with hæmoptysis, fibrinous pneumonia. Antipyrin was not given. In insomnia morphia and chloral were used.

DR. P. GUTTMAN, of the Moabit Hospital, also remarked on the severity of the epidemic and of the high death rate, which in his hospital amounted to twenty-five per cent. The participation of the sensorium was especially striking. The patients were not isolated.

PROF. VIRCHOW remarked that the sudden increase in typhoid fever in the early part of the year did not affect Berlin alone. It was very striking, however, that the parts most affected had the same water supply, the Stralauer. This was the old water supply in the east part of the city, which had its supply direct from the Spree, and was filtered through sand. He was also of opinion that dejections from typhoid patients were not dangerous after disinfection. The sewage farms showed this, where there was no increase of typhoid during the epidemic.—*Medical Press and Circular*, July 24, 1889.

Treatment of Pneumonia by application of Ice.—DR. FIEANDT, writing in *Duodecim*, a Finnish medical journal, states that he has now treated no less than 106 cases of pneumonia with ice, and with the best results. Though ten of the cases were of double pneumonia only three out of the whole number succumbed, notwithstanding that the epidemic was by no means a slight one. The method adopted was to apply over the affected lung an india-rubber bag containing ice continuously for from twelve to twenty-four hours after the crisis. In addition to the local treatment, the patients were given such medicines as are usually employed, that is to say, opium, ipecacuanha, digitalis, brandy, etc. The method has, we may remark, received of late some attention in England.—*Lancet*, August 10, 1889.

Treatment of Burns.—The *Pharm. Post* advocates the following treatment for burns: The wound should first be washed with an antiseptic solution, boric acid solution

(1 to 30) being preferable, and then covered with a piece of antiseptic paper which has been soaked in a solution containing one per cent. of boric acid and 5 per cent. of cocaine; over this absorbent cotton may be placed and a bandage applied. This dressing should not be removed for several days. The cocaine acts as an anodyne, and the boric acid will induce speedy healing.

Camphorated Soap.—The following is claimed by the *Revue de Thèr. med.-chir.* for July 15th, to be a most valuable soap for nervous, rheumatic, and herpetic patients:

℞.—Bitter almond paste	. .	60 parts.
Tincture of benzoin (saturated)		40 "
Powdered camphor	. .	8 "
White soap	. . . .	500 "

Mix in water bath, then pour into suitable moulds and cool.

Salpingostomy.—Although in the majority of cases of disease of both tubes, the most applicable therapeusis is their entire removal, yet in individual cases a more conservative method of treatment may be available.

This idea was carried out by Dr. Skutsch, of Jena, in the following case, which is reported in the *Centralblatt für Gynäkologie*, August 10th. The patient was a woman aged twenty-eight, who consulted Skutsch in reference to sterility and severe pains in the abdomen. Examination proved that the uterus was in normal anteflexion, and of usual size, its canal also being normally large. The left ovary was also of normal size; the left tube could be distinctly traced from the uterine end, and was found gradually to increase in size toward the ovary, and to end in a thick swelling. The tube seemed to be greatly distended. The same condition was discernible on the right side, the tube being likewise distended and swollen. The diagnosis arrived at was, closure of the abdominal ends of both tubes and double hydrosalpingitis. Skutsch concluded not to remove the tubes, but to empty them of their contents and to establish an artificial opening in the abdominal ends of the tubes.

At the laparotomy the diagnosis was fully confirmed. The ampullary end of each tube was opened, the contents, which proved to be a yellow serum, removed; then an oval portion of the wall, about half an inch square, was excised; the mucous membrane of the tubes, as well as the serosa, were united by fine silk sutures. Through the newly formed opening a sound could be easily passed into the uterus. Healing took place rapidly, and was unaccompanied by fever. From the day of the operation all pain left the patient.

Skutsch has given this operation the name of salpingostomy. When the tubes are filled with pus such an operation is very risky. The author by no means claims that the operation is a universally practical one; yet, in such cases where conservative treatment seems indicated, it may be allowable. An important feature in its favor would be subsequent possible impregnation; this, however, remains yet to be demonstrated.

Auditory Troubles arising from Use of the Telephone.—Quite a number of cases of auditory disturbances have been reported as following the constant use of the telephone. True, these are, as a rule, of a mild nature, yet are none the less troublesome to the patients. The symptom most frequently experienced is a constant buzzing in the ears. Deafness, usually temporary, has also been noted. The cause, Dr. Gellé says, may possibly be ascribed to a predisposed nervousness on the part of the subject, which may excite preëxisting aural trouble. Gellé, in *L'Union Médicale* for August 6th, cites several cases, in all of which the typical buzzing was noted, also vertigo in individual instances. He further has observed inflammation of the drum membrane, but is inclined to consider this secondary. In nearly all the cases mentioned, an abandonment of the use of the instrument brought about a speedy recovery.

A Dental Anæsthetic.—The combination of cocaine and antipyrine in solution is said to act as a powerful local anæsthetic upon the gums, and also upon sensitive dentine. The anæsthesia is more lasting and more complete than when cocaine is used singly.

Dr. Martin, in *L'Union Médicale* for August 8th, suggests the following formula, which he has used with great success:

℞.—Hydrochlorate of cocaine	.	gr. ¼.
Antipyrin	. . .	grs. vj.
Distilled water	. .	♏ xvj.—M.

Ice in the Treatment of Burns.—Dr. J. G. Carpenter, in the *American Pract. and News* for August 17th, highly recommends the treatment of burns with ice, or ice-cold applications. Two cases are cited where the treatment was attended by most speedy and marked success. The applications should be renewed frequently.

Ergot in Childbed.—Dr. Pinzoni, of Bologna, has made some interesting clinical experiments in order to determine, with something like precision, the value of ergot in childbed. He administered ergot systematically to ninety-one lying-in patients, generally in the form of about two grammes of the powder daily. Seventy-nine similar cases were treated without ergot. After comparing the series, he came to the following conclusions: Ergot has little or no influence on the temperature, at the most a slight rise is occasionally observed. It hastens the pulse a little, yet has no marked influence on the physiological slackening of the pulse observed during the first days after delivery. The physiological increase in the secretion of urine during the first days is favored by ergot. The involution of the uterus, according to Dr. Pinzoni's researches, is either totally uninfluenced by ergot, or slightly retarded. The escape of the lochia remains normal when that drug is given; but clots, as universal experience has proved, are more readily expelled. The lochia are seldom fetid when ergot is taken. Ergot delays the after-pains in primiparæ, and lessens them when they have already commenced. The secretion of milk is retarded and lessened by ergot, and sometimes completely suppressed. Ergot seems, in the belief of Dr. Pinzoni, to be a prophylactic against puerperal fever, an indirect antiseptic agent. When infection has already taken place, ergot appears, on the other hand, to hasten the entrance of the virus into the circulation. Dr. Pinzoni's researches appeared in the *Bollettino delle Scienze med. Bologna.*—*British Medical Journal*, August 10, 1889.

Myrtol, a New Antiseptic.—This antiseptic, if we may credit the statements of the *Giornale di Farmacia e di Clinica*, No. 17, 1889, is superior to any other. It is obtained by distilling essence of myrtle.

Myrtol is a colorless liquid, with a strong characteristic odor of myrtle. Its formula is C^{10} H^{16}. When given internally, both the urine and perspiration will smell of the drug and the former will frequently assume a violet color.

According to Professor Eich, myrtol is a most efficacious antiseptic in putrid affections of the respiratory tracts. The symptoms of headache and vertigo, which so frequently follow inhalations of turpentine, were never observed to follow the similar use of myrtol; neither does it produce any irritation of the mucous membrane, and is, in this respect, therefore superior to phenic acid and creasote. The best method for administration is in capsules containing two and three-tenths grains of myrtol; one capsule to be taken every two hours.—*Journal de Méd. de Paris*, June 23, 1889.

Chronic Nervous Urticaria Treated with Antipyrin.—DR. NITOT, in an article appearing in the *Journ. de Maladies Cutanées* for June, 1889, speaks of the value of antipyrin, in daily 8 grain doses, in the treatment of chronic nervous urticaria. Four cases were treated, and the following conclusions arrived at:

1. Chronic nervous urticaria is a malady which seems to be confined to the female sex.

2. Antipyrin usually effects a rapid cure in such cases. Old standing ones will, however, require longer treatment.

Treatment of Dentition.—The idea that all interference during primary dentition is harmful, is becoming antiquated. On the contrary, the infant can be saved from much unnecessary suffering by the use of simple hygienic and prophylactic measures. MONTI, of Vienna, although averse to any actual assistance being rendered in the cutting of the teeth, recommends the following course of treatment:

1. *During dentition*—the following mouth-wash should frequently be used:

℞.—Salicylate of soda, or boric acid . . . . 3 parts.
Distilled water . . . 200 "
Tincture of myrrh . . 2 or 3 " —M.

2. *After dentition*—the milk teeth should be frequently cleaned with a brush dipped in the foregoing solution and dusted with the following powder:

℞.—Carbonate of magnesia 10 parts.
White chalk } . . āā 30 "
Salicylate of soda }
Essence of menthol . . q. s.—M.

This may be substituted by the following, which will be found most agreeable:

℞.—Carbonate of magnesia } . āā 15 parts.
Medicinal soap }
Cuttlefish bone . . . 15 "
Essence of menthol . . q. s.—M.

—*Rev. Génér. de Clin. et de Thér.*, July 25, 1889.

Nephrectomy for Malignant Tumors.—DR. A. SIEGRIST has lately gathered together the statistics of nephrectomies for malignant tumors, which he reports in the *Centralblatt für Chirurgie* for July 27th.

In all 64 cases of malignant growths of the kidneys have been recorded; in three of these, the operation was abandoned after an exploratory incision had been made; the total number of nephrectomies for such growths is, therefore, 61.

Of these, 32 cases died directly in consequence of the operation, a percentage of 52.45 per cent. One patient died soon after the operation from preëxisting cardiac affection. Nine deaths resulted, not long after operation, from recurrence and metastasis. Of the remaining nineteen cases, five were still in health two years after the operation; two patients still well one year after; three six months, and one five months after the operation. The health of the remainder only lasted for a few weeks.

The percentage of mortality following the operation was far greater for the intra-peritoneal method than for the extra-peritoneal method; 57.89 per cent of the former to 23.52 per cent. of the latter. Contrary to this, the percentage of recurrences following the extra-peritoneal method was proportionally much greater than that of the intra-peritoneal method; 41.17 per cent. of the former to 5.26 per cent. of the latter. The growths operated for included 29 carcinomas (three being adeno-carcinomas), 34 sarcomas (with two adeno-sarcomas); in one case the nature of the growth was not given.

It will be seen that the number of successful nephrectomies for malignant growths is very small; all the same the operation cannot be condemned, as it is the only chance for recovery of cases which otherwise would inevitably only have speedy death before them. Still, every case of malignant growth of the kidney does indicate surgical interference, as in many such a procedure would be worse than useless. As an instance of this, one need but cite DR. THIERSCH, who, in three cases of this kind, felt forced to discontinue the operation after the primary incision had been made.

Microörganisms found in Lung Cavities.—Among the accessory microörganisms in lung cavities the bacillus of green pus has been found, also the micrococcus tetragenus. According to Klebs, species of sarcina have been detected in the gangrenous patches during the advanced stages of the disease. DR. CHARLES S. EVANS claims, in the *Centralbl. für klin. Med.*, July 27th, to have isolated six others, which he describes as follows:

1. A bacillus, not liquefiable in gelatine, fetid in bouillon, odorless in agar, of a flesh color on potatoes, 1.85 to 2.25 μ. in length, and 0.75 to 1.25 μ. in width, rounded at the extremities, and movable.

2. A staff-like, movable bacillus, plump and oval, about 1.25 to 2.5 μ. long, and 1 to 1.25 μ. wide, grayish-white on potatoes, fetid on gelatin and agar, non-liquefying, decomposes bouillon.

3. Bacillus fluorescens putridus.

4. An actively moving staff-like bacillus, 1.5 to 2.75 μ. long, and 0.6 to 1.0 μ. wide; growing upon potatoes without odor, of a reddish color, not liquefiable, grows in bouillon with stinking odor.

5. Proteus mirabilis (Hauser).

6. Proteus vulgaris (Hauser).

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, AUGUST 31, 1889.

THE DIETETIC TREATMENT OF CHRONIC BRIGHT'S DISEASE.

ABOUT seven years have elapsed since Senator's noteworthy paper, "On the Hygienic Treatment of Albuminuria," was reviewed in these columns. Perhaps the most striking paragraphs in the original article published in the *Berliner klin. Wochenschr.*, for 1882, were these: "At any rate, one will do well to forbid entirely the use of eggs in a case of persistent albuminuria;" again, "as to other albuminous articles of food, especially meat, if it be desired to remove an albuminuria, they are to be rigidly withheld." Equally emphatic was the language of Semmola, of Naples, who may be regarded as the leading authority on the same subject in Italy. Founded, as these statements were supposed to be and actually were, upon experiment and experience, they made a deep impression, and have influenced the dietetic treatment of Bright's disease more or less throughout the world.

The observations upon which these conclusions were based were such as the following: The experiments of Stokvis and J. C. Lehman, showing that if egg albumen is introduced into the blood, not only does it appear in the urine, but it is also accompanied by serum albumin; the earlier observation of Barreswill, that twenty-four hours after ingesting ten eggs, albumin appeared in his urine, and a similar experience by Hammond; also experiments by Stokvis and others on the feeding of animals; Senator's own observations on the urine of apparently healthy men, in which albumin made its appearance twenty-four hours after liberal ingestion of meat; and, finally, Semmola's experiments on animals with egg albumen injected under the skin, followed by albumin excretion over and above the amount injected, accompanied also by a decrease in the twenty-four hours' urea, and by anasarca and dropsy of the serous cavities—in a word, according to Semmola himself, the animals upon which he experimented became true examples of Bright's disease.

This experience, and the conclusions therefrom, have been recently offset by some observations of JULIUS SCHREIBER, published in the *Berliner klin. Wochenschr.*, of June 10. First, the results quoted of the subcutaneous injections of egg albumen are met with the statement that the same reasoning would exclude milk from the diet suited to Bright's disease, because when injected directly into the circulation it promptly appears in the urine. Second, Schreiber made a number of experiments consisting in the ingestion of large numbers of raw eggs, forty-two in three days, in addition to other albuminous food, and the urine remained without a trace of albumin. Third, to eight subjects of Bright's disease he administered from six to ten raw and cooked eggs daily, with similar negative results; in fact, in certain instances, there was an actual diminution in the albumin, so that he drew the conclusion that the ingestion by the stomach of liberal amounts of egg albumen was not followed by an excretion of albumin in healthy persons, nor is the albumin in the albuminuric increased. Nay, more, it would seem that the latter were more frequently favorably influenced thereby. Finally, a series of experiments in which the effect of a mixed diet, a meat diet and a milk diet, on the albumin of certain chronic albuminuric cases were compared, led to the inference that no definite conclusion dare be drawn as to the effect of any of these diets, the use of milk being sometimes attended by a decided increase, and at others by a slight diminution in the albumin.

In strong contrast are these results with the experience of both Senator and Semmola, and especially of the latter, who has seen the albumin entirely disappear from the urine entirely a few days after placing the patient on a milk diet. As the result of all of which, Schreiber concludes that an albuminous diet in any shape has not the disadvantages in Bright's disease so generally claimed for it; that patients under a milk diet eliminate no

more albumin than under a diet of albuminous substances, and that they do much better with an admixture of both, gaining in weight and otherwise improving; that no exclusive diet should be long persisted in, with a view to making up or substituting any loss of albumin by the urine; that a free supply of vegetables should be permitted, while strong spices and alcohol should be prohibited.

At first thought, these opposite results, which are doubtless correctly reported, are confusing and discouraging; but they, nevertheless, have a useful bearing upon the dietetic treatment of Bright's disease. In fact, they are no more at variance than those of remedies which are now allowed an acknowledged position in the treatment of other diseases. Here, as in other instances, time and clinical observation must come to our assistance and determine true value. That the use of a pure milk diet in albuminuria is at times attended by a diminution of albumin, we have proved in our own experience over and over again. That, on the other hand, such a diet is the best thing in all cases of albuminuria, we are equally assured is not the case, while it is as true that there are instances of Bright's disease in which a milk diet, whatever be its effect upon the albumin, is attended by a palliation of some of its most annoying symptoms.

In like manner experience has taught us that there are cases in which the admixture of meat with the other food is not only harmless but necessary to the well-being of a patient, while in others its use is attended by an aggravation of some of the most annoying and dangerous symptoms; all this quite independent of the amount of albumin in the urine, the cases with least albumin being often those which are most unpleasantly affected by a meat diet and most benefited by milk.

The whole explanation, in our opinion, lies in the fact—not overlooked by Schreiber, but still not allowed sufficient weight—that the proportion of albumin does not go *pari passu* with the retention of poisonous substances in the blood; in other words, the quantity of albumin is not *always* an index of the severity of the disease. It would seem to be the case that in certain forms of Bright's disease, notably chronic diffuse nephritis, there is a resistance to the onward movement of the blood through the kidneys which results in albuminuria, while the power of the renal cells to eliminate urea and allied products is not proportionately arrested. On the other hand, there are cases of chronic interstitial nephritis where from increased cardiac propulsion or other cause, the blood is driven through the kidneys, leaving behind but a small amount of its albumin, while the cells, or what is left of them, are unable to do their work, and the excrementitious substances accumulate in the blood until the uræmic explosion occurs. It is in these last cases that an albuminous diet is harmful, and milk, farinaceous substances, and vegetables, and in some cases milk only, not only relieve symptoms but also prolong the life of the patient. In the first category, on the other hand, a mixed diet, including meat and eggs, is not only harmless but necessary to avert the anæmia which sooner or later succeeds. Even here, however, it is good practice, and we believe it is sustained by the results, to temper the amount of proteid food, and not to administer it *ad libitum*.

From the standpoint of our personal experience, the results of Senator, on the one hand, and of Schreiber on the other, are quite compatible, and both have their proper application in the dietetic treatment of Bright's disease.

THE ANNUAL MEETING OF THE BRITISH MEDICAL ASSOCIATION.

THE fifty-seventh annual meeting of the British Medical Association was held in Leeds on August 13th to 16th, under the presidency of Mr. C. G. Wheelhouse, of Leeds. Over nine hundred members were in attendance. Dr. Hughlings Jackson delivered the Address in Medicine, Mr. Pridgin Teale the Address in Surgery, and Sir James Crichton Browne the Address in Psychology. The threatened bone of contention—the management of the *Journal*—which was brought to the fore by the unfortunate publication of the now famous script of the late Emperor Frederick, was quickly disposed of. It was pointed out that prior to the period when Mr. Ernest Hart took editorial charge of the *Journal* the yearly rate of growth of membership did not exceed forty; that since, and for some years past, the net growth had been at the rate of five hundred per annum, and now that figure even is exceeded, notwithstanding the very large proportion of the British profession who are already enrolled; and that this increase, which was coincident with the vast improvement which had taken place in the management of the *Journal* in the hands of Mr. Hart, was the best proof of the ability with which he had discharged his editorial duties. Upon vote the Association, with marked unanimity, expressed

its confidence in his management of the *Journal*. Thus this question was satisfactorily disposed, and the continued prosperity of the *Journal* assured.

The British Medical Association has certainly been fortunate in having had the benefit of wise counsel and able management. It has well maintained its reputation as a scientific body, and at the same time it has been an active factor in the advancement of the interests of the British profession, and with growing years its prosperity, power, and usefulness have steadily increased.

THE fifteenth annual meeting of the Mississippi Valley Medical Association will be held at Evansville, Ind., September 10th, 11th, and 12th. Those who will attend are advised to take a receipt for full fare to Evansville, Ind., that they may secure return tickets for one-third fare. The programme includes titles of nearly one hundred papers The indications are that the meeting will be larger than any yet held by the Association.

THE New York City Board of Health has declared war against the overcrowding of tenement-houses, and as a first step it is proposed to have positive proof as to the extent of the overpopulation. This is to be obtained by the taking of photographs at midnight by means of flash-light. Some of the inspectors are photographers, and have already tried the process as a means of demonstrating and perpetuating curious unsanitary conditions in their respective districts. And now the Board has decided to adopt this graphic method as a form of official record. It will assist in making up the history of "Hell's Kitchen," the "House of Blazes," and "the Bend," and will serve to illustrate future annual reports.

The Board will enforce another requirement of the tenement-house law, which is frequently ignored by the landlords, and which directs that water shall be placed on every floor of houses of that class.

DR. E. M. MOORE is at the head of an association in Rochester, N. Y., which has established a lake-side summer hospital for infants. The institution begins with accommodations for twenty patients and caretakers. It is located at the village of Charlotte, on Lake Ontario, with Dr. George W. Goler as attending physician. The primary design of the new hospital is to supply gratuitous treatment to children suffering from the diarrhœal troubles of the summer season, though not limited to them.

SOME young women college graduates, residing in New York City, propose to make a settlement in a bad tenement-house district, for the purposes of dispensing philanthropy and sanitation. Funds amounting to $3000 are in hand, and a large house of the olden time, near Ludlow Street, has been secured for occupancy next September. The young ladies will live there in a locality of squalor and hopelessness, doing what they can to instruct and relieve the poverty-stricken mothers and children. They will be accompanied by a female physician. It is expected that the shortcomings of the municipal officers whose duty it is to enforce cleanliness of street and domicile will be noted and reported with great particularity, and in a way that sanitary results will necessarily follow. These colonists must all be graduates, and no one will be received for a shorter stay than two months.

A NEW journal has sprung into existence in France, bearing the title of *Annales de la Tuberculose*. It is to be published bi-monthly under the editorship of DRS. FILLEAN and ISCOVESCO. It is virtually the creation of the Congress for Tuberculosis, recently held in Paris.

Merck's Bulletin, an admirable monthly publication giving the new discoveries, introductions, or applications of medicinal chemicals, and published at New York by the well-known manufacturing chemist of Darmstadt, whose name it bears, in the issue for June, just received, contains a very valuable table of maximum doses of 113 of the newer drugs, for the majority of which a statement as to the dose limits is not readily accessible elsewhere.

DR. EDWARD J. HARVEY, of Red Bank, N. J., had the satisfaction of restoring to life a drowned person, after rowing his boat a quarter of a mile to reach the point in the river where the person went down. His manipulations for the man's respiration, after he had brought the latter up from the bottom and lifted him into the boat, were performed right there in the boat. The scapular region rested upon one of the thwarts, while the head was dependent, nearly touching the bottom of the boat. This posture, with some pumping motions of the arms, liberated the liquid from the lungs, and breathing, but not consciousness, was reëstablished. Dr. Harvey

then rowed to the shore and his impromptu patient was given up to the physicians of the place, and recovery resulted.

If the rescue, in this case, had happened to have been made by any other than a physician, who was qualified to begin manipulations while floating in his little row-boat, it is altogether probable that the man's life would have been lost. The physician had the presence of mind, the knowledge, and the life-saving impulse, the combined exercise of which were necessary to make Dr. Harvey a life-saver of note.

SOCIETY PROCEEDINGS.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, June 17, 1889.

THE PRESIDENT, CHARLES S. WOOD, M.D., IN THE CHAIR.

DR. J. LEWIS SMITH read a paper on

IDIOPATHIC CONTRACTIONS, OR TETANY, IN INFANCY AND EARLY CHILDHOOD.

This disease, which has probably always existed, he said, was first brought to the attention of the profession in 1831 by M. Danee, who described it as it occurs in the adult. In the following year M. Tonnelé published an essay on tetany in which he designated it as a new convulsive disease of childhood. Having given a further *rêsumê* of the literature of the subject, he stated, that the term tetany is applied to a disease which is characterized by tonic contraction of muscles, commonly those of the extremities, but sometimes also those of the face or trunk, produced by causes external to the nervous system and usually of temporary existence. In tonic muscular contraction arising from disease of the brain, spinal cord, or their meninges, or of the nerve supplying the affected muscles, the contractions are not the malady itself, as in cases of tetany, but are merely symptoms of a disease located elsewhere.

Tetany may occur at any age, but is most frequent in infancy, in early childhood, and in early adult life. It is seldom that the most thorough investigation elicits any inherited predisposition to nervous or other diseases in cases of tetany. Rarely, however, multiple cases have occurred in families; from which he inferred that there may perhaps be an inherited neuropathic tendency. Nearly all writers assign the most important place in the causation to diseases of the digestive apparatus. Thus, Trousseau states that in the cases which have fallen under his observation diarrhœa has been commonly present (many cases met with in 1854 following cholera); but in one instance the cause seemed to be obstinate constipation.

In the following case, which he has recently had under observation, Dr. Smith said that constipation also appeared to be the chief cause. George C., aged seven months, living in a tenement house. Taken from the breast at the age of two months and fed upon condensed milk, with Nestlé's food once a day. Habitually very constipated, so as frequently to require assistance in obtaining an evacuation. Recently groups of muscles in all the extremities have undergone tonic contraction, producing the deformities shown in the accompanying cut. He has also had brief attacks of spasm of the

glottis, both day and night; causing for a moment the characteristic stridulous respiration. Otherwise he seems entirely well, though the mother states that at times he is feverish; this probably being due to the constipation. Attempts to straighten the fingers and toes elicit cries of pain, and the mother also says that at times both thighs and both legs are flexed, and that he resists attempts to straighten them on account of the pain. The treatment in this case consisted of bromide of potassium, in addition to measures for the relief of the constipation, and four months elapsed before complete recovery took place. It was noticed that when the treatment was perseveringly employed the contractions gradually diminished and then ceased, but that they returned when it was discontinued. During the four months that the tetany lasted the first tooth pierced the gums.

Erb states that all forms of intestinal disease may cause tetany, but that it especially occurs after protracted and exhausting diarrhœa. Gowers also regards diarrhœa as the chief cause. Dr. Smith has not found any recorded instance in which lumbrici or ascarides caused the contractions; but Gowers alludes to three cases in which they were produced by the tape-worm. Remarkable as it may seem, dentition *per se* is but seldom a cause of tetany, but in a case which Dr. Smith related, which he saw in consultation with Dr. E. G. Janeway, teething was regarded, after repeated and thorough examinations, as the chief cause of the trouble. The child was twenty months old, and the gums were found swollen and congested over the crowns of five advancing teeth, which appeared to be in nearly the same stage of development, and were evidently soon to protrude. The contractions continued for three weeks, when all or nearly all the imprisoned teeth escaped; and after this there was never any return of the trouble.

Tetany is more liable to occur in those whose systems are enervated by preëxisting disease than in those who are robust. Rilliet and Barthez, Erb, and Gowers mention a number of febrile affections as a sequel of which it is liable to occur, and Gowers also states that in young children attacked by it indications of rachitis are rarely absent. Another recognized cause of tetany is exposure to cold, and hence it has been regarded by some as in reality a rheumatic affection. In infancy and early childhood, however, other causes are apparently much more common than taking cold.

Ordinarily tetany occurs without any marked premonitory symptoms, but in some instances it is preceded by pain in the head or spine, vomiting without any previous indigestion or gastric derangement, and a general feeling of indisposition. Usually, in those old enough to express their sensations, it begins with tingling, burning, or other unusual sensory manifestations. The tonic contractions occur suddenly, and sometimes simultaneously in the upper and lower extremities. Rarely the contractions occur in the upper extremities alone, or in the muscles of the trunk. At first a feeling of stiffness is experienced, and this is followed by the tonic contraction, with the fixing of the affected part in a state of persistent flexion or extension. Usually, as regards the upper extremities, the contraction of the thenar and hypothenar muscles causes hollowness of the palms of the hands; the first phalanges of the fingers are flexed, the second and third phalanges extended, and the thumb adducted and flexed so as to press against the index finger or lie underneath it. The fingers sometimes incline toward the ulnar side, and sometimes are pressed against each other. Usually the hand is slightly flexed, as is also the forearm. The muscles which move the arm usually escape, but exceptionally there is adduction of the arm on the shoulder. The hand may be extended, instead of flexed, and all the points of the fingers extended; or they may all be flexed, and the fist closed.

The thighs may be adducted or flexed, the legs extended or flexed, the foot extended, forming a talipes equinus, and the toes flexed. In mild cases, or those of ordinary severity, the contractions are limited to the muscles of the extremities, and are more marked and persistent in those that move the hands, feet, fingers, and toes than in other muscles; but in severe cases the muscles of the trunk and head participate. Contraction of the abdominal muscles produces rigidity of the abdominal walls. Spasm of certain of the thoracic muscles occasionally occurs, causing dyspnœa, and even lividity; and in some of these cases of embarrassed respiration the diaphragm is probably involved. Opisthotonos, retention of urine, anteflexion of the neck from contraction of the sterno-mastoids, fixation of the jaws from spasm of the masseters, retraction of the angles of the mouth, stiffness of the tongue, and indistinct articulation, are occasional symptoms in severe cases.

The contractions render the affected muscles hard and unyielding, and the child cries from pain when attempts are made to straighten the limb. If the spasm be slight, some voluntary movement of the affected muscles is possible, but it is restrained and difficult. In severe cases voluntary motion is impossible. Unless the attack is very mild, pain is felt in the contracted muscles, such as every one experiences when a spasm occurs in the calf of the leg. It may occur in paroxysms with distinct intermissions, or without interruption, and it may vary at different times, probably from some variation in the degree of spasm. Certain subjective symptoms, such as numbness and tingling, which sometimes occur in tetany, may continue during the intermissions or remissions. After some hours or days the rigidly contracted muscles relax, and the disease disappears, except, perhaps, that a degree of stiffness remains. But the respite is usually of short duration. The spasms recur, and several successive recurrences and intermissions take place, running over months, before the disease is permanently cured. During the intervals in the contractions the affected nerves and muscles are, in ordinary cases, unduly excitable; so that sudden pressure or percussion causes some contraction. It was first noted by Trousseau that, as a rule, compression of the artery and nerve supplying the contracted muscles causes or increases the contraction. Dr. Smith said it was an interesting fact that in cases which he had observed the spasms did not cease in sleep, though perhaps the contraction of the muscles was not as great as when the patient was awake.

Gowers, Erb, and others have noticed that the electrical excitability of the nerve which supplies the contracted muscles is increased. When contractions are strong, œdema sometimes occurs, especially upon the dorsal surfaces of the hands, and Henoch attributes this to compression and consequent passive congestion of the veins. In severe cases perspiration sometimes occurs, and an erythematous redness may appear on the affected muscles. Occasionally, in acute attacks, the temperature is moderately increased, but ordinarily it is normal. Tetany does not usually affect the internal organs, but in two cases reported by German authors albuminuria was present for a brief time, and in one recorded instance the urine exhibited traces of sugar during the paroxysms. Occasionally, in long-continued cases, the contracted muscles undergo a degree of atrophy, which is attended by diminished electrical irritability, and Gowers states that general muscular atrophy has also been observed following tetany. Dr. Smith then related two cases, one occurring in his service at the New York Infant Asylum, and one seen in consultation by him, which he said might be regarded as typical cases of the disease.

In tetany the motor cells of the spinal cord and the axis cylinders are supposed to be in some way affected, but the pathology of the disease is still involved in great obscurity. As to its diagnosis, the bilateral and symmetrical nature of the affection is of great importance. The fact that certain groups of muscles on the two sides are affected enables us to distinguish it from the muscular contractions due to central lesions of the nervous system.

Moreover, the spasms in tetany, as has been seen, as a rule, are attended with intermissions, the nerves over the affected area have increased sensitiveness, and spasms may be produced by compressing the latter, thus forming a further contrast to the symptoms present in muscular contractions produced by disease located in the nervous centres or in the nerve supplying the affected muscles.

With regard to its prognosis, Dr. Smith said that tetany, whether intermittent, remittent, or occurring with little daily variation, sometimes soon ceases, and never returns. In other instances it does not cease entirely for months, although varying in severity at different times. Certain patients have attacks of it for years, with intervals of perfect health, and sometimes years elapse between the

attacks. During infancy and childhood tetany when uncomplicated ends favorably, with possibly now and then a rare exception. The few recorded cases in which death apparently resulted directly from this disease, have, as far as he has observed, all been in adults.

In the treatment, the cause or causes of the attack, so far as ascertained, should obviously receive prompt attention and be removed, if possible. The bromide of potassium is a most useful remedy for tetany in infancy and childhood, and it should be given in decided doses—as four grains every three hours for a child of from eighteen months to two years. Chloral, Indian hemp, and chloroform by inhalation are also useful in allaying the spasms. Chloroform is said at first to increase the spasms, but they cease when the patient is fully under its influence, though liable to return when the inhalation is discontinued. Hauber states that two cases which were not relieved by other treatment were soon cured by active massage employed when the patients were under chloroform narcosis. Stimulating liniments containing chloroform, applied over the affected muscles, have also been found of benefit in some instances. In his remarks on the electrical treatment of tetany, Gowers says that faradism is contra-indicated, but that good results have sometimes been obtained from the voltaic current. Gowers states that he also met with good results from digitalis given at bedtime in nocturnal tetany. When rachitis is present, as is often the case, cod-liver oil, lime, and syrup of the iodide of iron are indicated. Since so many cases originate from gastro-intestinal disorders, it is important that the diet should be bland, easily digested, and nutritious.

DR. J. R. MACGREGOR said that the affection in question seemed to occupy a position between the slighter spasmodic troubles we meet with and the permanent contractures attended with alterations of structure. It was evidently neuropathic in its nature, but whether such contractions could strictly be said to be idiopathic seemed to him somewhat questionable, since they might perhaps be dependent upon some cause not as yet recognized. It was natural that tetany should be excited by disorders of digestion in infants as the digestive organs became more and more elaborated. This gradual change in these organs occupied the entire first eighteen months of life, and they were extremely apt to get out of order during this period. In these disturbances dentition was also liable to manifest itself in an abnormal manner, and it seemed to him under these circumstances it might readily be instrumental in the causation of tetany.

INTESTINAL OBSTRUCTION; LAPAROTOMY; DEATH.

DR. THOMAS H. MANLEY presented a section of intestine, over four inches in length, removed by laparotomy from a patient suffering from intestinal obstruction. Low down in the left iliac fossa a knuckle of gut was found caught by a firm constricting band which completely obstructed the bowel, and two patches of ulceration being discovered on the peritoneal surface, it was decided to excise the affected portion. The patient was greatly exhausted when he was first seen, and he never rallied from the operation.

DR. J. G. TRUAX said that the patient was sent first to the medical wards of the Harlem Hospital with a diagnosis of enteritis. He recognized the case as one of intestinal obstruction in which surgical interference afforded the only hope of relief, and at once transferred the patient to Dr. Manley in the surgical wards. It seemed to him that possibly the patient might have recovered if Dr. Manley, instead of making a section of the gut, had contented himself with merely relieving it from the bands which constricted it.

FIRST CONGRESS OF THE GERMAN DERMATOLOGICAL SOCIETY.

Held in Prague from June 10 to 12, 1889.

(Concluded from page 135.)

DR. NEISSER read a paper on

THE STRUCTURE OF THE BACILLI OF LEPROSY AND TUBERCULOSIS.

DR. KAPOSI, of Vienna, made some

OBSERVATIONS ON THE LAST EPIDEMIC OF HERPES ZOSTER IN VIENNA.

He said that herpes zoster appears in the epidemic form in the months of March and April, and September and October, at a season when erysipelas and pneumonia are observed most frequently. This leads us to believe that there is an infectious cause, and this belief is strengthened by the fact that a patient only suffers once from the primary herpes zoster.

During the last epidemic, November, 1888, to February, 1889, out of forty cases of zoster, five only were really developed, while the others took the abortive form. The case of herpes zoster consecutive to an injury is, of course, to be entirely left out of this class. To this group he added a new form, the "zoster atypicus gangrænosus hystericus," photographs of which he presented. On a young lady of twenty-two there could be seen on both sides of the chest and on the upper portion of the abdomen several gangrenous spots of skin, having a length of three to eight centimetres (one and a quarter to three and one-eighth inches), of a linear or oval form, green color, with dentated borders; they were formed of several lenticular spots. In other places, still younger to the process, one could see that the necrosis commenced in the papillary body and chorion, while the epidermis remained intact. After the elimination of the necrosed parts, persistent suppurating ulcerations remained, extending deeply into the dermis. Moreover, small vesicles appeared around the necrosed portions, their centre being depressed and of a black or green color. The eruption had developed itself in about eight days, but the patient had already suffered on several occasions since her twelfth year, and regularly each year since the age of twenty, of the same disease, localized on the extremities, the face, the chest, and abdomen, where keloid-like cicatrices could be discovered.

Another young patient, fifteen years old, suffering from the same disease, presented a complete hemianæsthesia of the left side. He thought that this disease, which differs from Doutrelepont's spontaneous gangrene by the formation of nodosities and vesicles disposed in groups and by the cyclic course of the attacks, ought to be regarded as zoster gangrænosus hystericus developed on an hysterical basis, and the etiology of which must be looked after in a periodical alteration or special irritability of the spinal or cerebral vaso-motor centres.

DR. DOUTRELEPONT, of Bonn, said that his case of

spontaneous gangrene he at first thought was a variety of zoster, and he is more convinced of it. His patient is also a nervous case, and has even tried to commit suicide.

Dr. Chiari, of Prague, then read a paper on

VARIOLIC ORCHITIS.

He has observed in forty-five out of sixty-five cases that the parenchyma of the testicle is almost constantly, and especially in children, the seat of macroscopical alterations in the course of smallpox, alterations which he would be tempted to consider as analogous to the eruptive elements of the skin. By the aid of the microscope, he has been able to recognize in the testicle three typical zones of papules of smallpox: the zone of total necrosis, the one of the infiltration of the connective tissue and necrosis of the cells, and, finally, the zone of peripheric exudation. He has never observed any suppuration; the necrotic spots are soon absorbed; microorganisms have been met with in seven cases. All these observations permit him to affirm more strongly than ever that this orchitis is a specific manifestation of variola.

Dr. Joseph, of Berlin, then made some remarks on

CIRCUMSCRIBED ŒDEMA OF THE SKIN AND PAROXYSMAL HÆMOGLOBINURIA.

He had treated a young man, who for the past two years and a half was subject to circumscribed acute œdemas of the exposed parts every time he would expose himself to cold or wind; the œdemas would disappear after the patient had remained for one-quarter of an hour in the apartment. Last winter, having taken cold, he was seized by an attack of hæmoglobinuria; he took to bed, sweated as much as possible, and the next day was well again. This coincidence between the acute œdema of the skin and the paroxysmal hæmoglobinuria deserves consideration. This young man had taken a great deal of Tokai wine for over one year; and he should say that he had already treated a man of thirty-eight years of age, strongly alcoholic, who, after each excess of drinking, presented acute cutaneous œdemas.

Dr. Rosenthal, of Berlin, said that cases of acute circumscribed œdemas are not very rare, and generally these lesions are in connection with inflammatory parts. Unna had already drawn attention to a certain analogy which existed between acute œdema and urticaria due to venous spasm.

Dr. Neisser did not admit this opinion of Unna, and he is inclined to think that the œdema is more often due to an irritation of the vaso-dilatator nerves, the urticaria being then only a subacute œdema arising from the dilatation of the arterial vessels.

Dr. Behrend, of Berlin, thought he was the first to announce that circumscribed œdema was nothing else than a very extensive urticaria. This opinion had been confirmed by observations he had made in a patient who presented acute swellings analogous to typical eruptions of urticaria. As to the explanation of the pathogeny of the affection, he was unable to give it, for he did not belong to those who sought to ascribe all diseases of the skin to a nervous origin.

DIAGNOSIS OF POSTERIOR GONORRHŒAL URETHRITIS.

Dr. Jadassohn, of Breslau, recommends irrigations in the anterior portion of the urethra to recognize if the posterior portion of the canal is involved or not.

Dr. Finger, of Vienna, did not believe in urethral endoscopy, and he referred to the regurgitation of pus from the posterior portion of the urethra into the bladder in cases of posterior urethritis; and presented specimens of sediments obtained from the second portion of the urine in which he had found gonococci when he had to deal with posterior specific urethritis.

Dr. Grünfeld, of Vienna, believed that with the endoscope one can see every part affected in posterior urethritis.

ON THE VARIABLE TOXIC POWER OF MERCURIAL PREPARATIONS USED IN HYPODERMIC INJECTIONS.

Dr. Zeising, of Breslau, had made on rabbits subcutaneous injections of different kinds of mercurial preparations, and he had found that the results obtained were in proportion, not to the quantity of mercury used, but to the easy absorption of the preparation used. As regards the intensity of action of a drug, one can safely say, that the most easily absorbable substances are those that are very soluble; then come those which contain insoluble salts; and, finally, those made with the metallic mercury.

Dr. Lesser had observed in 12 cases, out of 500 injections made with different salts, serious intestinal symptoms. The objection to these insoluble preparations is that there is formed in the body a deposit of mercury, which progressively, and in a continuous way, infiltrated itself into the organism, and all of a sudden we might witness the appearance of a very marked mercurial intoxication.

Dr. Kaposi had had one case of death after the injection of the gray oil, subcutaneously introduced; the patient had received during seven weeks 215 grammes (over eight fluidounces) of mercurial oil, which amounts to 0.72 centigrammes (eleven grains) of mercury. The dosage of insoluble preparations still remains very doubtful, and their too extensive use brings on a deposit of mercury which may become very dangerous.

Dr. Neisser, of Breslau, thought that the criticism made against the injections of the insoluble salts of mercury was correct; but this does not mean that the treatment by unctions is without danger, for he had lately had two cases of such poisoning. Out of eight hundred individuals whom he had treated by injections of insoluble salts, he had had but one case of intense diarrhœa. He thought also that it was better to make the injections into the subcutaneous tissues instead of into the muscles.

Dr. Herxheimer, of Frankfort-on-the-Main, had given up using the preparations of calomel and yellow oxide of mercury on account of the severe pains produced. He had then employed the salicylate of mercury in intra-muscular injections and had had very good results.

Dr. Epstein, of Nuremberg, had treated, last year, forty-two patients with the salicylate of mercury, and he had never observed very serious intestinal troubles; in children he had used with success the thymolate of mercury. A fact worth mentioning was that we must not make subcutaneous injections of insoluble preparations in individuals suffering from phthisis, for in such patients a certain amount of fever will be produced.

Dr. Rosenthal, of Berlin, did not think that the

danger of the mercurial treatment is to be ascribed to the process used or the nature of the salt, but only to the drug itself and to its special action on the organism.

DR. PETERSEN said that when he began his service at the hospital all the patients treated by mercurial ointment were suffering from stomatitis; he then immediately resorted to injections and no more accidents were observed. He had treated 1300 syphilitic patients, of whom 500 were treated with calomel, and of which he had twenty per cent. of stomatitis; 500 were treated with the yellow oxide of mercury, very few cases of stomatitis occurred; now, he employs the salicylate of mercury, and he sees hardly any cases of stomatitis. As was mentioned by Epstein, he had seen tuberculosis develop more rapidly in tuberculous syphilitic patients treated by injections.

DR. DOUTRELEPONT said that when he injected calomel he occasionally observed intestinal troubles and often stomatitis; using now salicylate of mercury, he rarely met with those troubles.

DR. NEISSER did not think the use of injections of soluble or non-soluble salts a matter of indifference; he especially prescribes the former when he wants rapid action.

DR. PICK very much preferred the insoluble salts, on account of the less dangerous symptoms to which they give rise; but he thought that we ought to determine between these two important methods in the treatment of syphilis, injections and unctions, which one is to be preferred in certain cases, which in others.

DR. LESSER thought that injections of soluble are more dangerous than those of insoluble salts, for they are the cause of the introduction of a larger quantity of mercury into the system. Yet every method can bring on a serious intoxication if the dose is very much exaggerated or if no precautions are taken.

DR. WINTERNITZ, of Prague, appreciated the different methods of treatment of syphilis, and thought it necessary that one should study the exact quantity of mercury eliminated by the urine.

The Congress of 1890 will unite with the Dermatological Section of the International Medical Congress, which also meets in Berlin next year.

CORRESPONDENCE.

THE INTERNATIONAL CONGRESS OF DERMATOLOGY AND SYPHILOGRAPHY.

THE International Congress of Dermatology and Syphilography, held in connection with the "Universal International Exposition of 1889," in the city of Paris, was opened on the fifth of the current month, and has just adjourned after a week of serious work. From every point of view it may be regarded as a remarkable success. Never before in the history of medicine has such a large body of experts in cutaneous and venereal disease been assembled for discussion of the matters of interest connected with these disorders. Never before to a similar extent have the great teachers and masters of these subjects been associated in person. The well-known antipathy between the French and German nations, born of their late war, led to the fear lest the German dermatologists, whose absence would have given the present Congress far less of an international character, would not present themselves. Happily this fear was groundless, The response was as general as the invitation was generous.

The readers of THE MEDICAL NEWS will scarcely expect to find in a letter of this sort, which must necessarily be desultory in character, even the briefest *résumé* of the more than one hundred papers on skin diseases and syphilis, with the discussions which they provoked; as well as an epitome of the discussions, occupying fully eighteen hours, on the "general" questions, six in all, submitted by the Committee on Organization for consideration by the Congress in its morning sessions. I shall merely attempt here to give a hasty pen-and-ink sketch of the men who took part in this great work, and of the way in which they did it.

The Congress was held in a suitable place surely. The venerable St. Louis Hospital of Paris, "constructed in the reign of Henry the Great, fourth of that name, King of France and Navarre," has been so often described and visited by American students, that its ancient tiles, its grimy walls, and its quaint gable windows, are familiar enough at home. It was early in its history devoted to "pestiferous" diseases; and when its royal founder made its erection possible, he did a better work for future generations of his contrymen than with his "oriflamme" at Ivry, upon which Macaulay has dilated in his poetic measures. Skin diseases and venereal diseases are fashionable in and about "the St. Louis." The matron of the out-patient department greets one with a smile upon her lupoid features. A benign epithelioma ornaments the countenance of the guard. The military attendants have interesting lesions under their white trousers.

The Congress was opened in the large and comfortable hall of one of the central buildings devoted to the museum and library of the hospital. Its walls are constituted of the upper and lower cases, divided by a gallery, in which are displayed the magnificent collection of models of all diseases of the skin, fashioned by the hands of the distinguished Baretta. For this special occasion it was decorated also by festoons of the flags of all nations. The adjoining library, hall, and consultation-room, furnished ample facilities for registration and official purposes, as also for the duplication of sessions—dermatology being the order for the afternoon at some sessions in the larger hall, and venereal diseases in the smaller, simultaneously.

There were many notable men in view when Prof. Hardy called the Congress to order for its first session, and, was speedily honored by an election as its permanent president. On his left was the venerable Ricord, now ninety years of age, once the most decorated man in France, and even now, in these days of a French Republic, showing, when he rose to acknowledge the applause elicited by the mention of his name, the costly jewels of an order on his left breast. Here also were Fournier, Maurice, Jullien, Hallopeau, Diday, Besnier, Vidal, Brocq, and Barthélemy among the French; Malcolm Morris, T. C. Fox, Crocker, and McCall Anderson, as representatives of Great Britain; Kaposi, Neumann, Hans Hebra, Schiff, and Schwimmer, from Austria; Unna, from Hamburg; De Amicis and Pellizari, from Italy; Boeck, from Christiania; and dozens of others whose names are scarcely less known all over the world,

and from every country of the same. From the land of the leper; from the city where "the itch" most prevails; from the region where the "Biskra bouton" enlarges; and from the district where pellagra flourishes, they had come who best knew the history of these maladies. The United States of America were represented by Dr. James C. White, of Boston, who was honored by an invitation to preside at one session; Dr. James Nevins Hyde, of Chicago; Dr. Robert H. Morison, of Baltimore, and Dr. Klotz, of New York. In the course of the Congress, Dr. White read (in English) an interesting paper on the "Hereditary Dermatoses"; Dr. Hyde (in French) a paper entitled "Observations based upon the Statistics of Cutaneous Diseases in America," while Dr. Morison's paper was read for him by the Secretary (in French) "On the Formation of Pigment in the Skin of the Negro."

The fullest liberty had been offered to those participating in the sessions of the Congress, as to the employment of the language most familiar to each participant. But, as a matter of fact, the very general unfamiliarity of the French members with any language save their own, rendered it quite necessary to employ the French language in all general discussions. Prof. McCall Anderson, Dr. Crocker, and Mr. Malcolm Morris, addressed the Congress in English, but Pringle, Drysdale, and Wyckham all employed the language of the majority. One only, Unna, undertook to speak in German, but he elicited such a storm of opposition by this course that he at once betook himself to the French, and did not subsequently express himself in another tongue. It gives one an idea of the polyglottic education so common on the Continent, if one sees a dozen German physicians taking part in a French Congress and talking French to each other. One of them, indeed, when requested, translated the speech of an English member into French for the benefit of the Gallican members present unfamiliar with that tongue.

The first question discussed before the Congress elicited a wide difference of opinion as to the constitution of the group "lichen." There seemed to be but a small number of those engaged in the debate (including Hebra, Neumann, Schwimmer, Morris, Boeck, Besnier, De Amicis, Kaposi, Schiff, Jamieson, Unna, Vidal, Leloir, and Hallopeau) who accepted the American doctrines respecting the absolute differentiation of lichen planus and lichen ruber. Some of the Vienna gentlemen asserted very positively that they had observed typical lesions of each of these alleged diverse disorders in one and the same patient. The views of Jamieson were in accord with those expressed in his treatise, where a number of other affections, some even eczematous in type, are described as "lichenoid." There was no agreement reached as a result of this debate, but it served an excellent purpose. It brought the real leaders of dermatological thought and observation to the front. After they had measured swords in debate, they learned at least what and whom to respect. Besnier held his own superbly with the great masters of the Vienna school; Vidal proved clearly that the sceptre had not yet wholly departed from France.

The enormous facilities of the St. Louis Hospital and museum were gradually shown as the discussions went on to pityriasis rubra and the general exfoliative dermatoses, primary in character, which have been classed with it. And rarely, during the debate, while a speaker occupied the tribune, a patient was shown, his person completely exposed, exhibiting well-marked features of the disease under discussion, which was simultaneously illustrated by perhaps half a dozen excellent colored "moulages," and as many more aquarelles and colored lithographs.

Kaposi here placed himself squarely and positively on the old ground respecting pityriasis rubra first held by Hebra. Only an enormous experience could enable a man to identify positively the specific affection to which this name was strictly limited in its application by the great Vienna teacher. The large number of cases in which, with considerable redness of the surface of the skin, with fine desquamation, there was associated some infiltration, and even cachexia, were not cases of pityriasis rubra. If the patient, with these symptoms generalized, recovered, assuredly he had not suffered from such a malady. A fatal result was practically essential to the correctness of the diagnosis.

Of course, when the question under discussion related to pemphigus and the complex or multiform bullous dermatoses, the much abused and ably advocated "dermatitis herpetiformis" of Duhring, was sure to present itself. Its identity and special claim to recognition as a distinct disease were ably presented by Brocq. Never did a cause have a more logical, earnest, eloquent, and painstaking advocate. Brocq is a relatively young man of rather delicate appearance, who had really risen from a sick bed in order to do this duty. His speech was enforced (as so often during this eventful and fruitful Congress) by the presentation of a patient exhibiting perfectly typical manifestations of the disease as described by Duhring; also by the admirable series of "moulages" made by Baretta, illustrating other phases of the malady. Further, as if to clinch the position beyond peradventure, Dr. Duhring himself had examined this patient but a short time before, and had written a letter (which was read) completely identifying the disorder from which the patient suffered, as that which he has so elaborately described. It should be explained that the absence of this gentlemen from the Congress was due to an indisposition, in consequence of which he was confined to his hotel in London.

Here, also, after a full and exceedingly interesting discussion of the subject, Kaposi displayed that brave and persistent irreverence, which is a wholesome thing for any scientific body, if its apostle be only a well-trained gentlemen. He knew, he said, nothing about dermatitis herpetiformis. The patient, whom he had examined, presented to his view the symptoms of an ordinary pemphigus. He dwelt upon the variability of the several lesions which may be displayed in pemphigus; and practically refused to permit them to be considered apart from that category.

Brocq concluded with an earnest and powerful summary of the case. But, after all said and done, dermatitis herpetiformis may be said to have at last established itself fully on a sound basis in dermatological nomenclature, from the mere fact of its admission to such an important debate before such a large body of experts. Its fight has been fought; its victory not assured, but its ground is held. Being unconquered, the rebuff is for its adversaries. It will probably never include the large number of morbid conditions claimed for it by its enthusiastic advocate, whose name will always be associated

with it. Shorn of these, however, it will always be recognized as a special and distinct dermatosis. The credit is with America; and all those who have steadily believed in the future of American dermatology may well feel pride in the result.

Another patient, exhibited before the Congress, served to illustrate an excellent paper by Darier on "Cutaneous Psorospermosis." The body of this man was extensively covered with peculiar warty-looking lesions, evidently associated with proliferation of tissue in and about the sebaceous glands, which Dr. White, of Boston, recognized as identical with the affection lately described by him as a "keratosis follicularis."

Of other patients also exhibited, two, an elder and younger sister, were perfect illustrations of that exceedingly rare disease known by many names, including the "xeroderma of Hebra," the "progressive melanosis of Pick," etc. In these cases there is commonly a curious admixture of coincident symptoms, including discrete pigmentations, telangiectases, atrophies, and new growths. These patients were shown by Quinquaud, who has a remarkable facility in the line of clinical demonstration. His utterance is clear, emphatic, and unhesitating; with each sentence formed as though carefully studied in advance, and every word clean-cut as with a knife. His mind works in a logical and straightforward channel. The result is exceedingly happy. He looks as though he were almost idiotic in consequence of the intense concentration of all his faculties upon his subject; but he talks at such times as if inspired.

Some of Hallopeau's patients were scarcely less interesting. Two were in the premycosic stages of mycosis fungoides, one of these exhibiting, after several years of suffering, an extensive and pruritic erythematous involvement of the skin with only a few nodules of mycosis fungoides visible on the scrotum. One of his patients, fully described in a late memoir, is still in the hospital, but now wholly blind, a veteran syphilitic who had, after the production of a singular exanthem by ingested iodide of potassium, distinct cicatrization occur in the site of the departed lesions of the medicamentous dermatitis.

The Congress added largely to the literature of syphilis by the number and value of communications presented on this subject, as also upon all matters of venerealogy. The honors here were unquestionably carried off by Fournier, who received, after his admirable and thorough presentation of the subject of "tertiarisme" in syphilis, the longest and most prolonged applause of any speakers on all subjects. It was not due to his fine features and impressive presence, but rather to the admirable method of presenting his facts, illustrating by charts in the most graphic manner, the frightful preponderance of nervous syphilis among tertiary manifestations. Other papers by various authors covered effectually the ground from syphilis of the nose to syphilis of the vagina; from syphilis of the child to the same disease in the aged, including both Turk, Jew, and infidel. There were a number of important papers also on lepra, lupus, sarcoma, epithelioma, and tuberculosis.

Quinquaud read a paper describing his "hydradenoma," illustrated by faithful "moulages" and the patient from whom the casts had, some of them at least, been taken. However incredulous some of the members had been who had, before the demonstration, merely examined the casts and read the author's papers on the subject, it is safe to say that, after the session, many of them were really ready to admit that they had been confronted by a disorder with which they had been previously quite unfamiliar. As for the "pityriasis rubra pilaris" of the French, many examples of which were seen among the "moulages," it seemed possible, from observation of these after listening to the discussions, that some were forms of ichthyosis; some, of a superficial erythematous dermatitis; and some of a peculiar disease, perhaps distinct in character, occasionally associated with pilary disorder, to which the term pityriasis rubra pilaris could scarcely at all times be properly applied.

On the last day of the Congress it was voted to meet triennially hereafter; and, after a vote divided between London and Vienna, it was agreed that the next meeting, three years hence, should be held in the latter city.

The arrangements for entertaining foreign guests were all that could be desired. Dr. and Mme. Hardy received the members of the Congress at their residence on the Boulevard des Capucines on Tuesday evening. On Thursday evening the Municipality of Paris gave a magnificent entertainment to all the scientific congresses in session in the city, as well as to all the native and foreign students of science in the vicinity. The new Hotel de Ville, erected at an expense of nearly five millions and decorated at an expense of half a million of dollars, was thrown open from entresol to roof, and illuminated on the exterior of every floor with thousands of electric lights. It is estimated that ten thousand guests were in attendance. Four orchestras, a chorus of several hundred voices, and several large rooms devoted to refreshments, provided entertainment for the evening. The scene in the large salons was indescribably gay, in consequence of the varied costumes worn by the foreigners; the white turbans of the Mohammedans, the brilliant uniform of the officers of many nations, and the evening toilettes of the ladies furnishing bright and recurring contrasts.

The Congress was concluded with a dinner given to the foreign delegates by the resident members in the lower story of the museum of Saint Louis Hospital.

With this was concluded the largest, most successful, and most important convention of experts in skin and venereal diseases, from all countries of the world, that has ever assembled. There were two hundred and thirty-five in attendance. LANTERNE.

PARIS, August 10, 1889.

A WINTER VACATION TO THE WINDWARD ISLANDS.

IV.

IT requires many things to make any part of the earth's surface truly beautiful. The work of man, the manifold bounties of nature; the modeling of the earth when its plastic surface yields to the touch of the infinite Hand that makes all things well; heat, moisture, light—must all be infused with due proportion, to create a picture that shall live always in the memory.

Such a picture lay before us as the morning sun slanted through the defiles of the mountains and illuminated the Island of Grenada. The creeping shadows, the light stealing through the purple mists, the crenellated

hills, the towers and battlements of the graceful citadel, the red-tiled roofs, the groups of royal palms bending with exquisite grace from within the walls—mingled to produce a picture that almost made one believe that an enchanter's wand had been waved before one's vision, and that it was but the beauty of some exquisite necromancy made of the material wherewith poets dream and artists vainly seek to gather upon their canvas. But it was all there. A reality and an ideal. A picture created for the eternal glory of earth—beautiful Grenada.

When we landed Kingstown was in a ferment. It was Shrove Tuesday, when it is the custom of the negroes to masquerade in the streets. They traveled the streets in groups of five or six, each company arrayed alike as shepherds and shepherdesses, knights in tin armor and ladies in sweeping trains or soldiers with wooden swords and guns. They danced to the music of tom-toms, each group surrounded with dense crowds of spectators. In the afternoon the masquerade had developed into an orgy with gesture and motion so indecent that the ladies of the party were obliged to return to the steamer. The colored police were out in full force, especially about the market-place, which was densely thronged.

The town is most favorably situated for picturesque effect. It is built upon a peninsula that terminates seaward in a lofty crag, against which the surf rolls in with a grand dash of spray. Fort St. George crowns the summit with a sky-line of battlement and tower. It was built in 1710 and for the purposes of war is useless, but it is strong in the elements of beauty. Standing at the fort and looking landward the town is spread before you, bending over the crest of the ridge down to the peaceful waters of the bay upon one side, to the sea-front of the island on the other, where the Caribbean spreads its waves of unspeakable blue with its line of surf tumbling in nearly to the walls of the houses. Nearly all the buildings are roofed with red tile, which, with the variegated green of the foliage, affords a charming harmony and contrast of coloring.

I saw nothing of the ruin, decay, and poverty that Froude speaks of in his book, *The English in the West Indies*. I may say with old Père Labat two hundred years ago, "To live there was to live in paradise." A word about Froude and his book. He has succeeded in making himself cordially hated throughout the English West Indies. He is, I think, justly accused of being prejudiced and unfair, and describes the condition of islands that he never visited. From what I saw of the Windward Islands, I must say that his book is entirely unreliable. An answer to it has been published at Demerara, but the book was already out of print, and I was unable to get a copy.

The town is kept very clean by a system of drainage that appeared very nearly perfect for a hot climate. The drainage is exclusively on the surface in well-paved gutters, either in the middle or sides of the streets; every morning these are flushed out with water and swept with brooms. This is the plan in nearly all the Islands. The labor is generally performed by gangs of colored convicts under a guard of police. For a hot climate this appears the better way. Everything is in sight for cleaning and disinfection, and exposed at all times to the antiseptic action of air and sun. There are no sewers and traps to intercept and conceal filth in inaccessible places. That the method is a good one the good health of the Islands demonstrates. Yellow fever rarely gains lodgement to the extent of an epidemic. Smallpox is, however, the scourge of the Islands, and of which the people have great dread. Martinique had been quarantined against for over a year, and, as a rule, one or more of the Islands for the same reason is in that condition nearly all the time. Anything like general vaccination is impossible, as the negroes have a superstition against it.

After one of the most enjoyable days of the trip, at night we weighed anchor for the Island of Trinidad.

We were roused out of bed at gray dawn to see the *bocas* or mouths, the pass between the mainland of South America and the Island of Trinidad. All we could see were black rocks on either side through a thick veil of mist, which in a moment had blotted them out, when we were again in a world of fog. Before us was the Gulf of Paria. You enter it from the Caribbean by the Dragon's Mouth, and you may leave it, on the way to Demerara, by the Serpent's Mouth—another dangerous and romantic pass.

By the time the sun had dispersed the mist we were at anchor off the Port of Spain. This is the ground made famous by Charles Kingsley in *Westward Ho*. Buccaneer and forbau had gone, and before us lay a goodly city and about us a fleet of stately ships. The hills rose in a series of volcanic peaks, and on the plain at their feet was the city of the Port of Spain. A very pretty feature was the long line of cocoanut palms that grew at the water's edge. Aside from the shops, which were well stocked, the chief attraction was the coolies. They made a very picturesque addition to the usual street scenes. Those of my readers who have been to the East Indies know all about them, but as none of us had ever seen the coolie in the East, we spent a large part of the day in that quarter of the town. These poor fellows work under indentures to the government for five years. They are forced to labor. If they complain of being sick, they are sent to the doctor, and if found that they are not so, or only shamming, which they can do to perfection, they are sent back to work, and work they must or be fined. Many of them are under such arrears of debt that they will never secure their freedom. There was a settled look of hopeless misery upon many of the faces. The women were plump, and loaded with gold and silver coin and bracelets, their husbands having heaped upon them all their wealth. While the men were emaciated and naked to the waist, the women were strutting about in all the colors of a gaudy butterfly with bracelets from wrist to shoulder, necklaces of gold coin, and nose-rings. They were perfectly willing to sell their bracelets. I bought several from a woman who took them off as plump and pretty an arm as one would wish to see.

Trinidad has a population of several thousand coolies, many of whom are in trade. A jeweller sitting cross-legged before a little charcoal fire, built on the ground, was busy up to steamer time making us bracelets. He would make a very fine one out of a silver dollar, and charge twenty-five cents for his time. The coolies understood all about American coin, while the negroes would not touch it. It is owing to the enforced labor of the coolie that sugar planting is profitable at Trinidad and Demerara. The negro is perfectly content to look on. He does not love to work.

Hindoo priests were very numerous, taller and lighter colored than the others, clad in costly, many colored gar-

ments and well fed. They appeared to have unlimited authority. At one place we found a temple in full operation, after passing several which were closed. The building was octagonal in form with doors upon three sides. Opposite to the main entrance sat, cross-legged, a dignified-looking priest; before him, seated upon the ground, were two men pounding upon small drums; near by, seated in the same way, was a man teaching a boy to write. The man upon the platform twirled his thumbs, the people passed by in a steady stream and gave no attention. All day long the drumming never ceased and the people never heeded. I asked a negro, who told me that he was a Methodist, what it meant. "O! they's hired to do that, Sir; that's the way they has their praying done."

The Hindoo repays the contempt of the negro a thousand-fold. He belongs to a lordly race; slave as he is, he would not touch the body of a freeborn negro. And, inded, he has right upon his side; you have but to see them together to realize that he comes from a nobler race and is the better man.

The Port of Spain is counted among the hot places of the earth. It is shut in by the crests of the hills and mountains, which follow the trend of the coast. Before it, across the fresh water Gulf of Paria, is the wide and malarious delta of the Orinoco. The average yearly temperature is 80°. The health authorities are vigilant. The gutters are flushed, cleaned, and disinfected every morning, and in addition nature has provided a sanitary inspector who is ever on the watch. This is the large crow, as it is called here—a bird of that form and color, but as large as a turkey. I witnessed one of their sanitary operations near the landing on my return to the ship. As I sat waiting for the boat I saw that a dog lay upon the ground *in articulo mortis*. In a short time his struggles were over, and at the same time I observed a crow approaching him in a critical and guarded way as though he feared the animal might be sleeping, but to the expert eye the attitude was unmistakable, and it pounced upon him with a wide flutter of wings. Instantly from housetops, telegraph poles, and invisible regions of the sky the crows came in scores, and where the dog lay was a writhing, screaming, struggling mass of horrible black, and in a few moments nothing was left, not even bones. These birds are protected by law, but they are unpleasant and uncanny creatures.

ELY VAN DE WARKER.

NEWS ITEMS.

Organization of the International Congress of 1890.—The following delegates from the various faculties and medical societies of Germany will act as the Committee on organization of the International Medical Congress of 1890, and will hold their first meeting at Heidelberg in September.

The *Faculties* will be represented as follows:

Berlin, Prof. Virchow; Bonn, Prof. Binz; Breslau, Prof. Biermer; Erlangen, Prof. v. Zenker; Freiburg, Prof. Hegar; Giessen, Prof. Löhlein; Göttingen, Prof. König; Greifswald, Prof. Mosler; Halle, Prof. Hitzig; Heidelberg, Prof. Czerny; Jena, Prof. Kuhnt; Kiel, Prof. Heller; Königsberg, Prof. Lichtheim; Leipzig, Prof. His; Marburg, Prof. Schmidt-Rimpler; Munchen, Prof. v. Ziemssen; Rostock, Prof. v. Zehender; Strasburg, Prof. Jössel; Tübingen, Prof. v. Jürgensen; Würzburg, Prof. Schönborn.

The leading *Medical Societies* will be represented as follows:

Anatomical Society, Prof. Schwalbe, of Strasburg; Congress for Internal Medicine, Prof. Leyden, of Berlin; German Surgical Society, Prof. v. Bergmann, of Berlin; German Society for Gynecology, Dr. Martin, of Berlin; Ophthalmological Society, Prof. Becker, of Heidelberg; Society of Mental Specialists, Dr. Laehr, of Zehlendorf; Balneological Society, Dr. R. Brock, of Berlin; German Dermatological Society, Prof. Neisser, of Breslau; German Dental Society, Dr. Fricke, of Kiel; German Association of Physicians, Dr. Graf, of Elberfeld.

The local Medical Associations will be represented as follows:

Drs. Baumgartner, Fränkel, Crocker, Busch, Trendelenburg, Heidenhain, Carl Weigert, Kast, O. Boeck, v. Ziemssen, Wicherkiewicz, Kugler, Naunyn, Berlin, Leichtenstern, Fiedler, Pletzer, Schulz, and Schrickel.

French Hospitals in the Orient.—We learn from the *Union Médical* for August 17th that a French Medical Missionary Society is being formed in Paris. This Society intends to establish schools and hospitals in Africa and the Orient, in order to counterbalance the power of existing English and German Medical Missionary Societies, "which," the *Union Médical* supplements, "are created merely in order to combat the influence of French medicine, which has hitherto predominated." This is a new light on missionary enterprize.

The American Society of Microscopists.—The annual meeting of this Society began its deliberations August 20th, at Buffalo, N. Y. Dr. Lucien Howe presented a medical subject, dealing with microscopic growths on the normal and diseased eye. Dr. George E. Fell reported on some studies of the testicular solutions made according to the method of Brown-Séquard.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE TWO WEEKS ENDING AUGUST 24, 1889.

ROGERS, B. F., *Surgeon.*—Detached from U. S. S. "Alliance," and wait orders.

HARMON, G. E. H., *Surgeon*—Ordered to U. S. S. "Constellation," August 13th.

LOWNDES, C. H. T., *Assistant Surgeon.*—Ordered to the U. S. S. "Constellation," August 13th.

DECKER, C. J., *Assistant Surgeon.*—Detached from the U. S. S. "Lancaster," and granted four months' leave of absence.

BALDWIN, L. B., *Passed Assistant Surgeon.*—Detached from U. S. S. "Ranger," ordered home, and wait orders.

HARVEY, H. P., *Surgeon.*—Ordered to the U. S. S. "Ranger."

LOVERING, P. A., *Passed Assistant Surgeon.*—Ordered to the Receiving-ship "Wabash," at the Boston Navy Yard.

SIEGFRIED, C. H., *Surgeon.*—Ordered to the Naval Station at New London, Connecticut.

SCOFIELD, W. K., *Medical Inspector.*—Detached from the "Lancaster."

HIBBETT, C. T., *Passed Assistant Surgeon.*—Detached from the "Lancaster."

WHITE, C. H., *Medical Inspector.*—Ordered to the "Pensacola."

HESLER, F. A., *Passed Assistant Surgeon.*—Ordered to the "Pensacola."

CURTIS, L. W., *Passed Assistant Surgeon.*—Ordered to the "New Hampshire."

JONES, W. H., *Surgeon.*—Detached from the "Pensacola," and placed on waiting orders.

VON WEDEKIND, L., *Assistant Surgeon.*—Detached from the "New Hampshire," and ordered to the "Pensacola."

THE CLIMATIC TREATMENT OF BRONCHIAL ASTHMA.[1]

BY FREDERICK I. KNIGHT, M.D.,
OF BOSTON.

IF one seeks information on the selection of a suitable climate for an asthmatic patient, he will soon realize that no successful attempt has been made to establish indications for preference of one climate over another for any given case of asthma; that changes of climate have been made usually in an experimental way, and have been as likely to be attended with aggravation as relief to the symptom.

The chief cause of this is the mistake which has been made in trying to reduce all cases of asthma to one class, assuming that the ultimate cause and mode of development of this symptom were the same in all cases. This has led to the origin and promulgation of different theories, which have been in turn supported and abandoned. We find, in looking over the literature of the subject, that at one time asthma has been considered almost exclusively as a bronchial spasm of local origin, and treatment appropriate to this condition recommended; at another time, the theory of hyperæmia of local origin has received much favor; and at still another, the reflex origin (at one time of spasm, and at another of hyperæmia) has been dwelt upon.

This habit of the human mind, of looking at only a part of the truth, was characteristically urged by Dr. Daly in his paper at the last meeting of this Association. This is especially true of the medical mind, and the inevitable result of specialism in practice has been to increase this tendency.

The ease of error of the medical man is greater than that of the blind men in Tolstoi's fable, because, while he may soon learn to interrogate all parts of the animal brought to him for examination, he will also soon be made aware that there is a great variety of animals. The specialist is familiar with one kind of asthma, according to his field of practice. The asthmatics who go to a rhinologist are naturally those who have trouble in the nose; the asthmatics whose symptoms are wholly thoracic consult some one of repute in that field; and this leads to the result that Dr. Bosworth[2] tells us, that he has found evidence of intra-nasal disease in every case of eighty asthmatics on his note-books, in sufficient degree to warrant the conclusion that it exercised a powerful causative influence in the production of the asthmatic attacks.

It has also led Dr. Hyde Salter[1] to say that eighty per cent. of cases of asthma in the young date from some acute inflammatory affection of the lungs, and has led Berkart to put the proportion due to this cause as high as ninety per cent.[2]

The dermatologist would tell us, perhaps, that he had seen asthma almost invariably associated with eczema, and the syphilogian might say that he had never seen a case of asthma without syphilis. The fact is, that asthma is only a symptom, and the factors whose combination produces a paroxysm are not always the same.

I should agree to the combination given by Dr. Bosworth as applying to a large class of cases, including most of the hay-fever cases. This combination was: 1. The neurotic habit. 2. A diseased condition of the nasal mucous membrane. 3. Some peculiar atmospheric condition, which precipitates the paroxysm;—*i.e.*, we have a predisposing, a determining, and an exciting cause. In order, however, to make this applicable to asthma in general, I should consider it necessary to make the second and third conditions more comprehensive. The second might be stated as a morbid condition somewhere in the respiratory tract, it may be in the upper air-passages or in the lungs themselves, whose irritation shows itself by a reflex exhibition in the bronchial tubes. The third condition should be made to include not only peculiar atmospheric states, but also digestive derangement, mental disturbances, and other remote irritations which act by reflex on the bronchial tubes.

It should always be borne in mind also that we may have more than one of the conditions mentioned under the second and third classes operative at once. For instance, we may have nasal disease and some change in the lung structure coöperating in the same patient, and also more than one of the exciting causes operative at the same time. This should lead us to be guarded in prognosis, and not to be too confident of cure because we have detected a single factor which is capable of removal. Who has not

[2] On Asthma; its Pathology and Treatment. London, 1878.

seen asthma persist after removal of nasal polypi, or after removal of a patient from a pollen-laden air which seemed to be the exciting cause of the attack?

In regard to the coëxistence of different factors for the production of bronchial asthma it may probably be said that only the second and third are absolutely necessary, and that while the first (the neurotic habit) is a pretty constant factor, a paroxysm may be produced without it when the determining cause (second factor) is situated in the lung itself. In considering the effect of climate upon the paroxysm it can readily be seen that its effect upon each of the factors should be studied separately; and, if either factor can be eliminated or seriously modified by climatic change, then the attacks will cease.

It thus becomes more explicable why entirely different climates relieve different cases of asthma, or even the same case at different times. Who has not seen a patient completely relieved by change of climate for a number of years, perhaps, and afterward, the symptoms returning, be again relieved by another move, perhaps even back to the starting-point? Now, in such case it is very likely that the patient, while strengthened in one factor, was gradually weakened in another till the paroxysm was again developed, to be again prevented by variation of influence.

When, therefore, a case of bronchial asthma presents itself to us, and we are called upon to break the "vicious combination," we try to determine which of the essential factors is most easily removed or modified.

The third factor (the exciting cause) is the one which is apt to engage the attention first, and it may be oftentimes easily removed. When the exciting cause is atmospheric, it may be some variation in the proper constitution of the air, or it may be the presence of accidental emanations, as the pollen of plants, the odor of animals, or animal or vegetable products. When the latter condition obtains and is once recognized, the patient may be able to keep himself out of the reach of the excitant, and, as is well known, an army of hay-fever subjects keep themselves well in this way by an annual exodus to exempt districts.

The well-known susceptibility of asthmatics to paroxysms in the country as compared to the city may likewise sometimes depend upon the presence of vegetable or animal emanations in the country air. In other cases it seems to be the atmosphere containing the most carbonic acid which affords the most relief; hence, the old, crowded portions of the city are looked upon by certain asthmatics as the abodes of bliss. This accords with the recent reports of cases of "dyspnœa" relieved by inhalations of carbonic acid gas.

A change in the density of the air sometimes affords marked relief. It is well known that removal to a high altitude relieves certain cases. These may be such as have for a determining cause some morbid condition of the bronchial area, in which a slight superficial hyperæmia and relative internal anæmia may relieve the paroxysm, and the variation in pressure at different altitudes may be enough to determine this. Instances of digestive derangement and nervous disturbance as exciting causes of asthmatic attacks are too well known to need illustration. I once had a gentleman patient recently married who almost always had an attack on sexual intercourse. I had another patient who could stop an attack by gambling for high stakes.

In regard to the possibility of so modifying the second factor (a morbid condition somewhere in the respiratory tract, which may be called the determining cause) that the combination shall fail, it may be said that this is sometimes easy and sometimes impossible. When the lesion is accessible to operation, as in the nose, this may be easy; when it is below the reach of operative methods, it may be very difficult or impossible. Perhaps the most brilliant results in the latter field are seen in the cures wrought by the potassium iodide. This remedy is especially efficacious in those cases in which there is evidently a catarrhal inflammation of the bronchial mucous membrane. These cases are also quite susceptible to a proper change of climate—*i. e.*, such a change as we have reason to believe would benefit the bronchial or pulmonary lesion. As to the possibility of so modifying the first factor as to prevent the attacks, I should say that while we may sometimes be successful in warding off the paroxysm by fortifying the nervous system with good hygiene and specific tonics, we will be less successful in this mode of attack than in either of the others. So, also, we may occasionally, in cases in which the neurotic factor is a prominent one, succeed in so modifying it by change of residence as to effect a cure in this way.

So it will appear that in climatic, as in medical, treatment we must make our application to the ascertained condition of the patient, as far as it is possible to diagnosticate this, and not to the name of a disease. There is no climate which is good for all cases of asthma, and we must carefully consider, when a patient presents himself for treatment, the nature of these three factors in his case, and which of them we intend to modify, and how far change of climate may be able to aid us in this.

A CYST OF THE PHARYNGEAL BURSA.

BY JONATHAN WRIGHT, M.D.,
OF BROOKLYN, N. Y.

THE name pharyngeal bursa, first given to a structure often found in the naso-pharynx by Mayer, is, in the light of more recent researches, probably a

misnomer, inasmuch as it implies that an anatomical structure of that description exists in the normal naso-pharynx. As such it was regarded by Mayer, Tourtual, Luschka, and, in recent years, by Tornwaldt.[1] Ganghofner suggested the name recessus medius in contradistinction to the recessus laterales of the pharyngeal tonsil, as more in keeping with its anatomical character. The former term, however, has become so fixed in the minds of laryngologists and is so in accordance with the form in which it comes under their observation, that it would be useless to attempt a change of name.

Mayer's[2] description quoted in full by Bloch is as follows:

"This pharyngeal bursa exists as a sac in the mucous membrane, covering the body of the sphenoid bone behind the choanæ, or rather, immediately behind the perpendicular plate of the vomer. Occasionally this sac reaches a size large enough to hold a cherry-stone. I have occasionally found it double or divided in the median line by a septum. . . . Occasionally there is an opening into the sella Turcica or into the body of the sphenoid, but usually this is so small that one might easily take it for the nutrient canal of the bone."

Luschka agreed with Mayer and regarded it as a remainder of fœtal life, a remnant of the pharynx, and connected with the hypophysis cerebri. He stated that it was not found in all subjects.

Dursy, Ganghofner, and Schwabach studied the subject from an embryonal standpoint and have pretty conclusively settled its true character. They have explained the manner in which the condition arises, which was stated by the earlier writers and by Tornwaldt and others in later years to be a normal structure. Ganghofner described the so-called "bursa pharyngea" as a more or less deep depression or cavity in the mucous membrane of the naso-pharynx, posteriorly in the median line and just anterior to the tuberculum pharyngeum. Its first indication in a three months' embryo is a little fossa about the size of a pin's head, a slight depression in the mucous membrane.

In the newborn the fossa is one or two millimetres deep and at the bottom is occasionally seen a little ridge or fold. In children two or three years old this furrow-like depression has developed into a marked recess between the median folds of the naso-pharynx, and usually has an oval or elliptical opening. He denied its connection in any way with the hypophysis cerebri.

Schwabach says:

"Both in preparations with marked formation of folds as well as in those where it is lacking there can be found in the median line, at the end of the median furrow, occasionally a little depression of about the size of a pin's head, which is usually bounded posteriorly by a thin fold of mucous membrane; but this never has any opening which could be regarded as the mouth of a sacciform diverticulum. In other preparations the median furrow ends, posteriorly, quite flat, without the trace of any depression."

He states further, that probably what Tornwaldt found was nothing but the median furrow of the pharyngeal tonsil, which, in some cases, by the adhesion of the surfaces of the median folds through inflammation, is converted into a canal open at one or both ends. When the mouth of this canal becomes closed we may then have a retention-cyst formed of varying dimensions. It is possible for this to occur in other parts of the pharynx where the folds of the pharyngeal tonsil lie in close apposition. I believe, from clinical observation, that this is the true explanation of this much-debated anatomical point. The frequency of inflammation in the post-nasal space is an ample explanation why such good anatomists and clinical observers regarded its results as a normal condition.

Czermak, the father of laryngoscopy, was the first to see (in September, 1860) in the rhinoscopic mirror the image of a cyst of the post-nasal bursa. He gave a good description of its appearance, but, of course, was ignorant of its true character. Eighteen years before this, Mayer, as we have seen, had described them from post-mortem investigations. Von Troeltsch, in 1859, described a cyst found in the naso-pharynx of a subject who had died from the effects of various aural troubles. Luschka also speaks of having found post-nasal cysts. Zahn, in 1885, described three cases of post-nasal cysts found post-mortem, and gives a full microscopic and macroscopic description of them.

Up to this date these are all the cases I can find mentioned in literature. Tornwaldt then brought forward his work on the pharyngeal bursa which has attracted such wide attention and commendation. He reported having seen in two years 45 cases of cysts of the pharyngeal bursa out of the 202 cases of disease of this bursa. This large number is certainly very surprising, and he attempts to explain it by the suggestion that the attention of special workers in this field had not as yet been called to the affection.

Although many observers in the last four years, since the appearance of Tornwaldt's paper, have written on the inflammations of the pharyngeal bursa, the assertion of Tornwaldt in regard to the frequency of cysts in that situation has not been supported. Walb, who is an enthusiastic admirer of Tornwaldt's paper, and who gives a careful report of forty cases of disease of the bursa, says he has never seen a case of cyst formation, while the proportion of Tornwaldt's observations is one cyst out of five cases of

[1] Tornwaldt claims elsewhere (Deutsch. med. Woch., Nos. 23 and 48, 1887) that he left the question of its anatomical character open.

[2] It is but fair to say that I have had to depend upon the very numerous and extensive reviews of the monographs of Mayer, Tourtual, Luschka, Tornwaldt, Ganghofner, and Dursy, as the originals were inaccessible to me.

bursal disease. I have made inquiry of many American laryngologists, and I have not as yet found one who has ever seen a case of true cystic growth in the situation of the post-nasal bursa. I am, of course, very far from believing that further inquiries would fail to elicit a different answer, but it is impossible for me to understand the frequency of cyst formations reported by Tornwaldt, to whom, however, is due the great credit of directing the attention of specialists to diseases of this region. Lehman has lately reported a large congenital cyst. Srebrny and Schaeffer each report one case of bursal cyst. The latter author, as well as Mégevand and Suchannek, with many others to whom it would be superfluous to refer, have made long and, some of them, valuable contributions to the subject.

For the thorough examination of the post-nasal space much patience, skill, and experience in the use of the rhinoscopic mirror are frequently necessary. The finger is the most reliable means of diagnosis in intractable cases. I have faithfully and persistently tried many kinds of palate hooks and palate retractors, and, though I am still open to conviction on the subject, I have about arrived at the conclusion that where you need a palate retractor you cannot use it, and where you can use one you do not need it.

In the case reported below, and which will serve as an excuse for what has gone before in reviewing the subject, the size of the cyst is certainly very rare, however frequent the smaller ones may be. Notwithstanding the amount of post-nasal obstruction in the case, however, the patient suffered remarkably little inconvenience from it. I may, furthermore, remark that this is the only case of the kind I have ever seen, though I have examined, since my attention was called to it two years ago, between two and three thousand cases of nasal or laryngeal troubles.

A. M., æt. seventeen, by occupation a bookkeeper, presented himself in May, 1887, at the Demilt Dispensary. His family history was negative. He had bronchitis (?) when small. He has always been more or less subject to sore throat with external "swellings" on the sides of the neck. He has been troubled for some time with excessive expectoration and dropping in the back of the throat. Occasionally his nose is stopped up. He breathes a great deal through his mouth. While annoying, none of his symptoms has ever been distressing. He is a well-nourished boy of fairly healthy appearance. His expression is somewhat vacant, his voice a little husky, and his hearing not acute.

Examination shows large tonsils which are diffused, stretching down to and being continuous with the large glands at the base of the tongue, and with the post-pharyngeal wall, which is thickened and has at times a dry and glazed appearance. The tonsils also extend high up between the pillars of the fauces. On account of this obstruction no posterior rhinoscopic examination can be made. The anterior nares are comparatively free. The vocal cords are somewhat congested.

By the continued and persistent application of the galvano-cautery to the tonsillar hypertrophies, after many weeks an amount of room was gained which allowed me to see that the pharyngeal vault was much lower than normal, and that the post-pharyngeal wall almost touched the soft palate. On introducing the finger, the pillars of the fauces grasped it with a powerful constricting action which was very marked, but I was able to map out fairly well a large, smooth, globular mass extending from the vault near the septum down on to the post-pharyngeal wall. It was of about the size and shape of a pecan nut, with its long axis from above downward. The walls seemed thin, and there was distinct fluctuation. On very moderate pressure backward with the back of my finger the cyst suddenly gave way with an almost audible snap. A clear, slightly viscid fluid could be seen trickling down the post-pharyngeal wall.. The finger could now be inserted into the interior of the cyst cavity, and the walls were felt to be thick at their base, thinning out to the point of rupture.

They were continuous with the pharyngeal mucous membrane, in the layers of which the cyst had evidently developed. No adenoid vegetations could be made out, either with the finger or with the rhinoscopic mirror. By means of post-nasal forceps large portions of the cyst-walls were removed from time to time, but, unfortunately, no microscopic examination was made. By means of galvano-cautery and the cutting forceps the pharynx was gradually cleared out. For a long time there was great thickening of the pillars of the fauces and distinct ridges—median folds (?)—could be seen on the mucous membrane at the former site of the tumor. There was soon a decrease of the secretions which had annoyed the patient, and he was able to breathe freely through his nose. For a long time after the operation, on gargling, the fluid would always pass into his nose. This, however, disappeared as the thickened condition of the faucial pillars abated. The patient was under treatment for nearly nine months, and when last seen, a few months ago, he had a fairly normal pharynx, though the tendency to catarrhal inflammations on exposure to cold was still marked.

NOTE ON INTRA-THORACIC GROWTHS DEVELOPING FROM THE THYROID GLAND.

BY WILLIAM OSLER, M.D.,
PROFESSOR OF MEDICINE, JOHNS HOPKINS UNIVERSITY, BALTIMORE.

IT has been shown that portions of thyroidal tissue may be met with anywhere from the base of the tongue to the heart, and in regions lying between these points the so-called struma tumors may be found, or even in rare instances within the trachea. Thyroidal growths also occur within the thorax, most commonly sub-sternal in position, and connected directly with the gland. Of these a number have been described (Virchow, *Geschwülste*, Bd. 3). More rarely tumors develop from the deeper portions or aberrant bits of a lateral lobe and extend into the chest, forming large intra-thoracic growths.

A most remarkable case is reported by Dettrich (*Prager med. Wochenschrift*, No. 31, 1887). In a woman, aged sixty, who had suffered for some time with cough and hæmoptysis there was found, filling the greater part of the right side, a cystic tumor the size of a man's head. It was covered by the parietal pleura and naturally caused great compression of the lung. Above, it was connected with the right lateral lobe of the thyroid. The cyst had yellowish-brown contents and contained cholesterin. Kretschy (*Wiener med. Wochenschrift*, 1877) describes a sarcoma of the thyroid, four and three-quarters inches in length, which formed an extensive mediastinal tumor passing to the level of the ninth dorsal vertebræ.

In the following case, No. 702, Post-mortem Records, Montreal General Hospital, there was a tumor similar in situation to Dettrich's, though not so large:

The patient, a woman, had died with symptoms of purulent bronchitis. There was no special emaciation. Occupying the top of the left thoracic cavity, outside the pleura, was a mass the size of a large orange, closely attached to the œsophagus. The arch of the aorta lay on the right side, the left subclavian passed directly over it and the left carotid passed just beside it. There was no special connection with any thoracic organ, though filling completely the top of the left thorax. There was a large bronchocele, the left lobe of which was in contact with the tumor and could not be isolated from it.

On section, it consisted of a series of imperfectly separated cysts containing a yellow-brown fluid in which were plates of cholesterin. The upper part of the tumor was firm and hard; some of the septa had calcified, others had a fibro-cartilaginous consistence.

The relations of this mass, its anatomical character, and the nature of the contents of the cysts, identical with that which is found in so many cases of old bronchocele, leave no question that it had developed from an outlying lobule of the left thyroid.

In connection with the case of Kretschy, above referred to, a somewhat similar instance was reported by me a few years ago (*Montreal General Hospital Reports*, Vol. I., 1880):

A girl, aged sixteen, had been under treatment for what appeared to be ordinary bronchocele. It had grown with great rapidity. There was marked difficulty in breathing and the question of tracheotomy was considered, but, as the dyspnœa became easier, the operation was deferred. Death occurred suddenly. Post-mortem, a tumor was found which involved exclusively the left lobe of the thyroid and formed a large round mass eight inches in circumference; above it extended to the level of the thyro-hyoid ligament, while below it passed down beside the trachea to the bifurcation. From behind, the mass had an elongated, somewhat oval shape; the lower end rested upon the left bronchus. Along this surface it measured one and three-quarters inches in length. At the upper right angle of the mass in front was a small thin remnant of the left lobe capping the tumor, the tissues of the two blending, not separated by a capsule. The right lobe of the thyroid was of normal size and appearance. Histologically the growth consisted of small lymphoid corpuscles.

I reported this case as one of lympho-sarcoma of the deep cervical glands involving the thyroid and simulating goitre, but I have no doubt now that it was a case similar to Kretschy's, in which the growth developed from a thyroidal lobe with extensions down the trachea.

INSTITUTIONS FOR THE TREATMENT OF PULMONARY CONSUMPTION IN THE UNITED STATES.[1]

BY PAUL H. KRETZSCHMAR, M.D.,
CONSULTING PHYSICIAN TO THE GERMAN LUTHERAN HOSPITAL OF BROOKLYN, N. Y.

PHTHISO-THERAPY has not made any decided advances during the last year, although the use of hot air by means of inhalation and the internal administration of pure vegetable creasote have claimed considerable attention of the profession, and both possess a certain degree of value which entitles them to further investigations and clinical trials. Our knowledge in regard to the mode of contagion, and with it the power to prevent the disease, has largely increased. Thanks to the careful investigations of Dr. George Cornet, of Berlin, we know to-day that

[1] Read before the American Climatological Association, June 25, 1889.

the phthisical patient *per se* is *not a source of danger* to his surroundings, and that pulmonary consumption is spread broadcast principally by carelessness and ignorance.

The question whether or not consumptives should be treated in institutions conducted for that special object has been discussed both here and abroad, and, while the sanitarium treatment is considered now as giving the best possible chances for recovery from consumption in its early stages, by the profession in Europe, there seems still to exist considerable difference of opinion on that subject among physicians in this country. Dr. George Cornet's experiments will do much to strengthen the case of those who advocate sanitarium treatment for consumptives, and they must necessarily help to overcome such opposition as was expressed recently by my friend, Dr. Samuel A. Fisk, in the president's address read before the Colorado State Medical Society, entitled "The Cottage Plan of Treating Consumption in Colorado."[1] Dr. Fisk does not by any means advise "cottage treatment" such as will be spoken of in this paper, but he declares himself in favor of treating consumptives in open health resorts rather than in institutions established for that purpose.

Dr. Fisk makes a fatal admission to correctness of the views he expresses, by stating and describing a number of cases which occurred in his own practice where great harm was done by over-exercise, and adding that such irreparable injury might have been guarded against in a properly conducted sanitarium. Dr. Fisk, and with him most practitioners who are honest in their opposition to special institutions for the treatment of pulmonary consumption, seems to overlook the fact that overtaxation of heart or lungs is one of the greatest dangers to which consumptives are exposed, and many lives of patients, doing apparently well, are lost by it. It is probably true, as Dr. Fisk states, that the results obtained in Colorado are excellent, but does that prove that sanitaria are not needed there? Would not the excellent results obtained in Colorado be still better if there were fewer cases where lives were sacrificed by mismanagement?—"cases which recur to each of Dr. Fisk's hearers."

The arguments which he uses against sanitarium treatment are by no means new. They are: 1, that patients do not like to be under constant supervision and control; 2, that a cheerful mental condition has a great part to play in effecting a recovery, and that it is inadvisable to congregate invalids where their thoughts are constantly employed in comparing notes with fellow-invalids and where they are subjected to the depressing influence that necessarily surrounds disease; and 3, that a congregation of phthisical patients render any air, aseptic in itself, very foul and septic. In framing these arguments Dr. Fisk must have been unconsciously influenced by a desire to place the *existing* conditions of his own State in the best possible light.

The first objection raised by Dr. Fisk shows that he does not yet recognize the personal control of consumptive patients—extending, as it should, to the smallest detail of every-day life—as a *conditio sine qua non* for giving them the greatest chances for a cure, though his own cases, which suffered so much by overexercise, etc., should have taught him the lesson.

The second and third objections might be used with just as much force against any *open health resort* where a large number of consumptives live in search of health—as in Denver, Colorado Springs, Georgetown, Aiken, Davos, Mentone, etc.; as a matter of fact, the third objection might very properly be used in favor of sanitaria treatment over open health resorts, where the patients live in badly arranged hotels or boarding houses, and where little or nothing is done to prevent the possibility of having the air loaded with tubercular bacilli, due to the carelessness of patients or their attendants. In a letter to the writer, dated May 12, 1889, Dr. E. L. Trudeau, of Saranac Lake, discussing Dr. Fisk's paper, describes the means employed at the Adirondack Cottage Sanitarium to prevent expectorations from becoming a source of danger to the inmates, and says:

> "The proof that with these restrictions no injury results to the patient, lies in the fact that my results are *better at the sanitarium than at the hotels*, and Dr. Fisk's argument, though plausible theoretically, falls to the ground when the most practical test—that of actual results—is applied."

In regard to another argument used by Dr. Fisk, Dr. Trudeau says:

> "His other objection—namely, that much depression of spirits must result from seeing so many others suffering from the same disease, is not, in my experience, supported by facts. I find that my patients at the sanitarium suffer from depression no oftener than those I have in private practice. The former seem to recognize the fact that they are 'all in the same boat,' that a disinterested effort is being made to save them by persons who have extensive experience in the matter, and, as a rule, they aid the physician cheerfully in his task. During the last five years only three patients left the sanitarium on account of home-sickness."

Dr. Trudeau makes this strong statement: "*If anything is to be done for those who are both poor and consumptive, it cannot be done outside of an institution*," and, after a very careful study of this subject, I have arrived at convictions which induce me to say, even stronger than Dr. Trudeau, *If anything is to be done tending to restoration to health for those who are consumptive, whether rich or poor, it can be*

[1] THE MEDICAL NEWS, May 4, 1889, p. 480.

accomplished with the greatest promise of success in a properly located and rationally conducted institution.

To bring about the best results, such institutions should be erected in regions whose climatic influences are known to be favorable to consumptives, places where consumption is known to be rare among the natives, in a moderately high altitude, not close to large cities, in the neighborhood of evergreen forests; they must be located so as to be protected from severe wind-storms; they should have enough cultivated path immediately around them to make exercise possible during all seasons of the year; sunshine and shade should be in proper proportion; the drainage must be perfect, and the water of the purest. The cottage or pavilion system seems to be best adapted to answer all the requirements; all buildings must be erected with their special object in view. The management of such institutions should be intrusted only to physicians of ability, large experience, and great love for their special work.

One feature which is more difficult to overcome than others is the tendency of patients to leave the institution long before they have secured all the benefits the sanitarium can give them. Patients should never think of staying less than seven or eight months, and they should know that six or eight weeks' residence at the very best of institutions will be of no permanent benefit whatsoever. Changing places on account of the season is not advisable as a rule.

Sanitaria for the cure of consumption have existed for many years in Germany, where Dr. Herman Brehmer started his now celebrated place in Goerbersdorf thirty-five years ago, and where successful institutions are now in operation in Falkenstein in the Taunus, at St. Blasien in the Black Forest, at Reiboltsgrün in Saxony, at Rehburg in Westphalia, in St. Andreasberg, and in Blankenbain in the Harz mountains. In this country Dr. J. H. Tyndale made an effort about ten years ago in Manitou, Colorado, and Dr. H. Gleitsmann before him, in Asheville, N. C., to establish similar institutions, but both failed from lack of professional support.

The interesting paper read by Dr. Alfred L. Loomis before the Medical Society of the State of New York, in 1879, on "The Adirondack Region as a Therapeutical Agent in the Treatment of Pulmonary Phthisis," and the very favorable results obtained personally by Dr. E. L. Trudeau, during a residence for over ten years in that portion of the Empire State, induced a number of benevolent ladies and gentlemen, under the lead and guide of Dr. Trudeau, to make an effort for the establishment there of an institution for the treatment of phthisical patients of limited means, and, in 1884, a moderately sized main building, two cottages (each of which accommodates two patients), and a stable were erected, and given the name "The Adirondack Cottage Sanitarium." Thanks to the philanthropy and the unselfish work of Dr. E. L. Trudeau, and to the kind support given to him by Dr. Alfred L. Loomis and others, this establishment has grown from year to year, and consists to-day of an enlarged main building—two wings having been added to the original—and eight fully equipped cottages, with three more almost completed, thereby offering facilities for over fifty patients. The feature which distinguishes this from other institutions of the same kind is the fact that the patients are not crowded together in one or two palatial houses, but that they live almost in the open air, in small cottages scattered over quite an area. These cottages are but one story high, elevated from the ground enough to prevent them from becoming damp, with a veranda in front and partly around each; they are supplied with running water, and with open fire-places. The smaller cottages are planned for two patients, the larger ones for four; the latest of these buildings all have a general sitting-room and a separate one for each patient. The partitions between the bedrooms are of mason work, and reach to the ceiling, while those dividing the sitting from the sleeping department are only seven feet high, thus allowing free circulation of air throughout the whole building.

The location of the Sanitarium is a very pleasant one, about 1750 feet above tide-water, covering an area of over eight acres, about one mile from Saranac Lake and seven miles from Paul Smith's; it is situated on a bluff commanding a grand mountain view toward the north and east, well protected from the prevailing eastern winds. The Chateaugay Railroad, running from Plattsburgh to Saranac Lake, a distance of seventy-three miles, was opened about one year ago and has removed one of the very few objectionable features of the Adirondack Cottage Sanitarium, its inaccessibility. Saranac Lake can now be reached from New York *via* N. Y. Central Railroad, almost without change of cars, within seventeen hours, or the trip may be made by Troy steamers which leave New York at 6 P.M. and reach Troy early in the morning, enabling one to be at the Sanitarium about 5 P.M.

The drainage is simple and efficient. The earth closet system is wholly in use and the material is removed to a distance at frequent and regular intervals. All the water is derived from a spring half a mile distant and is brought through iron pipes to the Sanitarium, reaching the second floor of the main building by gravitation only. All the meals are taken together in the airy drawing-room in the main building; a large supply of pure milk is derived from the cows belonging to the institution, and patients are allowed to drink it *ad libitum* whenever they desire to do so, whether at meals or between them.

Three meals are served daily and the usual bill of fare is about as follows: Breakfast, at 7.30 A.M., consisting of oatmeal or hominy and milk, beefsteak, chops or bacon, potatoes, bread and butter, coffee or milk. Dinner, at 1 P.M., soup, fish or fowl, or roast meat, two vegetables, pudding or fruit in season, milk *ad libitum*. Supper, 6.30 P.M., broiled meat or fish, or hashed meat, eggs, bread and butter, porridge, milk, fruit when obtainable. Alcoholic stimulants are very little used, and, contrary to the very pronounced view of all German observers, not at all in febrile cases. When the circulation is not readily excited and where no marked flushing follows their exhibition, they are moderately prescribed, usually in the form of whiskey or beer at meals. Patients are never allowed to use stimulants at their own discretion.

The climate of Saranac Lake does not differ materially from that of other parts of the Adirondack wilderness, except that the temperature during the cold season is remarkably low and steady, almost all changes from December to April being below the freezing-point. Much snow falls, and windless, cold, snowy days are a marked feature of the climate. January of this year was considered especially warm, the highest temperature recorded was 39° above and the lowest was 12 degrees below zero. The rainfall is a little above the average for New York State, amounting to about 55 inches.

The prevailing winds are westerly and southerly, and very windy days are the exception. The lower the mercury falls the less wind there is usually and the dryer the air becomes, so that exceedingly low temperature, such as 20 degrees below zero, is well borne by the patients. There is a dry period during the summer when little rain falls and the days become hot, while almost without an exception the nights are decidedly cool, and even during the hottest season there are but few nights when a blanket is not needed.

With the closest attention to hygienic matters, the main reliance in combating the disease is placed on the climatic influences and the life in the open air, this part of the treatment being carried out most thoroughly. Patients are encouraged to live out of doors and are gradually accustomed to inclemency of weather until they go out without regard to bad weather. Winter and summer they often sit—in winter thoroughly wrapped up—from six to eight hours in the open air. As the fever diminishes they are allowed to exercise, but not until then, and always moderately.

The drug treatment is considered as secondary, but is used to meet indications. Dr. Trudeau writes:

"Antifebrin is more used than any other drug, and is considered a valuable help in the restoration of the patient by increasing the capacity for taking food and diminishing the waste by its marked influence on the fever. It is often prescribed for months in 5-grain doses, usually taken at 11 A.M. and 5 P.M. Distinct improvement, more or less permanent, has seemed to follow the use of this drug in about forty per cent. of the cases treated. Next to antifebrin, creasote is perhaps more in use here than any other medicine; unlike antifebrin, it does not agree with almost all consumptives, and its use is restricted by the tolerance of the patient's stomach; when, however, it can be taken in large doses, four or five drops three times daily, a great improvement, not only in the subjective, but in the physical signs as well, has seemed to follow its exhibition in about fifteen per cent. of cases. If it disagrees with the stomach it is never given, even in small doses. Arsenic, cod-liver oil, and digitalis are also prescribed when indicated. The pneumatic cabinet is in daily use at the Sanitarium. Its use is resorted to mostly as a means of expanding the lungs and favorably influencing circulation and digestion in febrile cases in which malnutrition and debility are prominent features, and not as an appliance for the antiseptic treatment of pulmonary consumption."

The actual results obtained at the Adirondack Cottage Sanitarium are of very gratifying character, and compare favorably with those reported by others. A decided and important effect of treatment and climate is observed in the weight of most of the patients; the average gain for six months' stay at the institution is from nine to thirteen pounds. Perhaps the most remarkable effect has been observed in regard to one of the most frequent and dangerous complications of pulmonary consumption —hæmoptysis. Among eighty-three patients treated at the Sanitarium during the last year not a single hemorrhage occurred, and only four cases have been recorded since the institution began to receive patients four years ago.

Up to the end of 1888, 146 consumptive patients have been treated, and the results have been about as follows: Deaths 4, or not quite 3 per cent.; failed steadily 25, about 17 per cent.; stationary or slightly benefited 38, about 26 per cent.; disease arrested 63, or 43 per cent.; and cured 16, or 11 per cent.

Dr. Trudeau writes about these statistics:

"These figures are not, perhaps, thoroughly accurate, but they express on the whole the results, the classification adopted being necessarily a somewhat arbitrary one. Under the heading of cured cases come those in whom both the rational and physical signs of pulmonary phthisis have entirely disappeared; under that of arrested, those cases are put in whom the rational signs of phthisis have been steadily absent for several months with a return to normal strength, the physical signs, though abnormal, being interpreted by the observer as indicative of arrest in activity of morbid processes. This classification is made necessary by the fact that when most patients reach this stage the necessity of earning a livelihood compels them to return to their former occupations. No doubt a fair proportion of these would have ultimately come under the head of 'cured' had they been able to persist in the treatment."

The results of the last year are especially gratifying; of eighty-three patients, two, or 2½ per cent., have died; ten, or 12 per cent., continued to lose ground

and returned to their homes; eight, or 10 per cent., have improved; sixteen, or 20 per cent., have been so restored as to be able to resume again their various occupations, and twelve, or 14½ per cent., have been cured. The success in curing over 14 per cent. of consumptives is remarkable, and speaks highly for sanitarium treatment in general and more especially for that adopted at the Adirondack Cottage Sanitarium. Not to depend upon the patient's memory regarding important instructions, the following short, plain, and decided rules are placed in the hands of every inmate:

Out-of-door Life.—Patients gradually accustom themselves to leading an out-door life, that is, to remaining eight to ten hours in the open air each day. This should be done gradually, and at first the clothing should be heavy and the exposures to cold or inclement weather moderate in duration. Little by little the open-air sittings and walks are to be increased until the entire day is spent out of doors in all kinds of weather. In stormy weather the sheltered side of the verandas should be used for walking or sitting. When feverish, patients are urged to go out and remain sitting on the verandas well wrapped in suitable clothing.

Exercise.—*Violent* exercise is injurious. When feverish, patients will do well to make as little exertion as possible. *Fatigue*, when induced in persons still having active disease, is sure to be followed by loss of appetite, fever, exhaustion, and even sweating. Severe exercise in hot weather is injurious and may be dangerous. Patients will be informed by the physician how much exercise their case requires.

Food.—If unable to eat at the regular meal hours, patients will do well to drink milk every four hours.

Expectoration.—Patients are required ALWAYS to use the large spittoons in the public rooms and on the verandas, and the pasteboard ones in cottages; the latter should be burned every day in the stoves or fire-places. *Expectorating in handkerchiefs or on the floors, or even on the grounds in the immediate vicinity of the buildings, is strictly prohibited.*

It has been found that while moist sputum is harmless, when it becomes dried it will rise as dust, and may be inhaled. The above directions are given to guard against this result. Patients, for their own welfare and in order to assist in their rapid recovery, *will strictly observe these rules*, and will be liable to dismissal for wilful disobedience in this matter, which involves not only their own welfare but that of others.

Stimulants.—Stimulants are not allowed except under medical advice. No smoking is allowed at any time in the public rooms or on the piazzas. Patients are requested not to smoke at all unless permission is given by the physician.

The actual results obtained at the Saranac Lake Sanitarium place it in the front rank of institutions of similar character, but it stands before the world as unique, worthy of the highest praise, regarding its monetary affairs. Without endowment of any kind, depending simply upon the voluntary contributions of those interested in its work, strengthened and supported by the untiring labor of love of Dr. E. L. Trudeau and his associate, Dr. C. T. Wicker, of Saranac Lake, the Sanitarium is a charitable institution of the highest and noblest type. The patients are by no means paupers, but the price for board and medical attendance is fixed at such a low figure, five dollars per week, that people of moderate means are thereby given a chance to enjoy the great benefits of this remarkable institution. The promoters and supporters of the Adirondack Cottage Sanitarium deserve the thanks not only of those who have directly been benefited by a stay there, but of everybody who can appreciate the excellent service done by it to suffering fellow-beings.

The board of trustees, consisting of Dr. Alfred L. Loomis, Dr. E. L. Trudeau, Mr. Charles M. Lea, and Mr. Daniel W. Riddle, have charge of the finances of the institution, and their different annual reports show that from 1884 to February, 1889, they have received

From voluntary contributions		$29,565 50
From patients, for board		18,515 28
Total		$48,080 78
Of this sum they have spent for land, buildings, and other permanent investments	$20,674 42	
For board of patients and other running expenses	25,033 24	
		45,707 66
And have a cash balance on hand of		$2,373,12

The failure of Dr. Gleitsmann in his efforts to establish a sanitarium in Asheville, N. C., did not prevent Dr. Carl von Ruck from making another trial in the same direction, and it is now a little less than one year since Dr. von Ruck, who had conducted until then a small private hospital for throat and lung diseases in Norwalk, Ohio, successfully, transferred his institution in an enlarged form to Asheville, N. C. The climate there has been the subject of frequent discussions and it is generally agreed that it is almost an ideal one for phthisical patients. Notwithstanding the fact that large numbers of consumptives sojourn thither in search of health, the death-rate from that disease is a remarkably low one: only one native died last year of pulmonary consumption, a negro who came originally from South Carolina, while ten phthisical patients (visitors) died during the same period.

The Ashville institution is known as the Winyah Sanitarium and receives consumptives only. It is located outside of the city proper at the upper end of the natural water-shed of the city, and the inmates escape one of the few objectionable features of Asheville—the dust arising from the unpaved streets during the hot months. The building was originally intended for a hotel; it is furnished with steam heat, hot and cold water in all rooms, ventilating shafts, bath-rooms; it has a wide and high veranda, two hundred and fifty feet long, with west, south, and eastern exposure, and with the newly cultivated park immediately surrounding is well adapted to its purposes. The walks leading up the mountain

are graded in such a way as to make the ascent easy, even for weak patients, the rise being one foot in twenty-five, with plenty of seats scattered all over the place. Pine forests are in the near neighborhood and are daily visited by patients; oak covers some of the surrounding mountains; the soil is clay and sand, free from all marshes and standing waters.

Dr. Dettweiler's system of *resting* in the open air for as many hours as possible, in all kinds of weather, is carried out thoroughly by Dr. von Ruck; easy reclining chairs are provided, together with blankets for the cool season, and many patients are kept lying on the veranda the largest part of the day, until they show sufficient signs of improvement to warrant actual exercise in the open air. The same care which is exercised in the Adirondack Sanitarium regarding the expectorations of phthisical patients is used in Dr. von Ruck's institution, and it is said that the patients are so thoroughly informed of the danger to which they expose themselves and others by carelessly expectorating upon the floor or the sand covering the paths that there is a complete coöperation on the part of every individual. Of course, spittoons are provided in large numbers, but the patients are further supplied with Chinese paper handkerchiefs to be used instead of ordinary ones, and to be burned after being used once or twice. The spittoons are filled with antiseptic solutions and they are emptied and *thoroughly cleaned* at frequent and regular intervals. Patients are reminded never to swallow sputa.

The general nutrition of the patient is carefully attended to, milk is furnished *ad libitum* and can be had at any time; if koumyss is preferred, the latter is given in place of milk. The diet is the same as any first-class hotel would furnish, except that instead of pies good puddings are given and fried dishes are, as a rule, avoided. Especial attention is given to the condition of the digestive apparatus and gastro-intestinal derangements are considered the obstacles which *must* be removed before any progress can be made in the patient's condition. Dr. von Ruck agrees with the writer as to the vital importance of the strictest supervision of each and every patient, and no general plan of treating patients is adhered to; each case receives careful attention and the treatment as indicated by existing conditions. In general it may be said that Dr. von Ruck takes a position midway between Dr. Trudeau and Dr. Dettweiler regarding the use of stimulants; malt liquors are not at all used in the Sanitarium, but whiskey or brandy of known quality is prescribed in febrile cases. Light wines are allowed at meals, but the habitual use of stimulants is not encouraged. The daily administration of from ten to fifteen gallons of oxygen is resorted to in many instances and has proven to be of value in aiding digestion and developing some appetite in cases where all other means had failed. The pneumatic cabinet is used and considered of special value in phthisical cases where the disease is arrested, or nearly so, where the power of the respiratory muscles is to be augmented to increase expansion and capacity. It is claimed that good results have been obtained by antiseptic inhalations. The use of creasote has been abandoned and Dr. von Ruck states that after many careful and painstaking trials he has never been able to satisfy himself of any favorable influence upon the disease.

From October, 1888, to the end of May, 1889, fifty-one patients have been treated in the Sanitarium, and the results obtained are such as to satisfy the expectations of the most enthusiastic advocate of sanitarium treatment as the best means of curing consumptives.

During the month of December, 1888, Dr. H. M. Wilson, Jr., of Baltimore, undertook to establish a mountain sanitarium for phthisical patients in Tannersville, Catskill, but his efforts were not crowned with success and after a few months of existence the establishment was closed again.

In Colorado two sanitaria are in progress of erection, one at lake Palmer, to be built and conducted by a stock company of which Dr. Charles Dennison, of Denver, is the vice-president, and the other one in Colorado Springs, under the management of Dr. S. E. Solly, of that city.

An enterprise somewhat different from other existing sanitaria has been suggested and strongly advocated by Dr. J. H. Sloan, of Santa Fé, New Mexico. "A course of treatment by which the cure of phthisis pulmonalis is made not a probability but a certainty, in a majority of cases—in fact, in all cases where the disease is not too far advanced."[1] Dr. Sloan, having observed the great benefit which some of his consumptive patients have derived from camping in the mountains near Santa Fé, has determined to adopt out-door camp life under the supervision of a painstaking physician as "a positive cure for consumption." He claims that it is essential to spend at least eighteen months in the neighborhood of New Mexico, and he proposes to have his patients spend fourteen of them in tent life in the mountains in hunting, fishing, etc. The other four months, which are the intervening months of winter and early spring, are to be spent at the St. Vincent Sanitarium, in Santa Fé, when the patient will be surrounded by every comfort. Dr. Sloan has addressed a number of prominent physicians in the East and has laid his plans before them. The principal objection to this proposition is the expense entailed.

[1] Letter by Dr. Sloan of November 10, 1888.

SIMPLE TESTS OF THE OCULAR MUSCLES.[1]

BY B. ALEX. RANDALL, A.M., M.D.,
OPHTHALMIC AND AURAL SURGEON TO THE EPISCOPAL AND CHILDREN'S HOSPITALS, PHILADELPHIA.

SINCE the time when Donders and other pioneers first gave us a full picture of the matters of refraction, accommodation, and convergence, the questions as to muscular insufficiencies have occupied a considerable share of attention. Seizing these subjects with his usual vigor, v. Graefe handled them in a manner which has made them in great measure his own; and later discussion has shown that in many respects we can hardly do better than to return to him for solid teaching on this very important matter. Partial tenotomy, and other forms of "graduated tenotomy," rediscovered in this later day, were thoroughly tested by him; and the rules of procedure which he left us were the results of thorough winnowing of the useless from the valuable.

He gave us three practical tests, intended more especially for the study of insufficiencies of the interni, but two of them well calculated to serve in other cases. The first of these was as to the ability of the patient to fix with both eyes an object such as the finger-tip, as it was approached in the middle line to within a few inches of the eyes—a test that is often of value in determining which of the interni is the weaker—but a confessedly rough test, which, even with Landolt's "ophthalmodynamometer," rarely fails to show 16–20 metre angles of converging power in even very weak muscles.

The second test consists in causing the patient to fix upon an object held in the middle line a little below the horizontal at a convenient near point and watching for any wandering of one eye, in front of which a card is held. Modify his procedure by substituting a *fine* fixation object, such as a pen-point, for the "moderate-sized" penholder which he suggested, and we have an admirable test—ready, simple, and accurate. The *rationale* of this and of the third test, more generally called by v. Graefe's name, is clearly set forth in his paper; but his tests as there given are rather crude for the certain attainment of the end in view. We are to make trial of the *balance* which subsists between accommodation and convergence—"ein Gleichgewichtsversuch"—and the prime essential to any constant result is that the fixation-object shall be such as to hold the accommodation fixed and unvarying. It is a delicately formed forefinger which needs any accurate accommodation to see it with fair clearness; yet how often we see the test applied in this way! It is small wonder that we hear little as to the value of results thus gained. But try the test in the other form—use a fine pen-point as the fixation-object, insist that the patient fix it so as to see the tip sharply, and make quick movements of the covering card from one eye to the other, and you will obtain results of great practical value and reliability. I do not remember that I have ever discovered by any other test a muscular insufficiency which this test had failed to reveal. Further, it is a test which is *quantitative* as well as qualitative; and in hundreds of cases the *degree* of insufficiency thus estimated and recorded has proven at most only 1° away from the result as measured by prisms. Roughly speaking, each millimetre of movement of the deviating eye corresponds to 2° of insufficiency as measured by the prisms; but so far as the interni are concerned, each jerk with which the fixation is accomplished is to be multiplied into the foregoing result. Thus, if the covered eye move in some 3 mms. to fix, but do so with three distinct impulses, our estimate of the degree of deviation would be, not 6°, but 18°. Of course, no such rough rule-of-thumb will enable every one at the first trial accurately to estimate degrees of deviation; but a very moderate amount of practice in the comparative use of this and other tests will prove to any one that it is as accurate as it is easy.

No one who has had any experience in testing muscular insufficiencies will need to be told that he must repeat his tests several times and average his results—the first few trials may show a relation of accommodation and convergence that is wholly fictitious and unnatural. Neither this nor any other test will give at all times equal or infallible results; but I ask for the method—always easy of application, without any spirit-levels or other paraphernalia—a reasonable and conscientious trial at your hands; and do not believe that you will often fail to discover and approximately measure even minute deviations, whether vertical or lateral. To the possible objection that long practice has made me especially expert in correctly estimating, I may reply that I was as accurate as now, when, after a year's practice, I demonstrated the method in v. Arlt's clinic in 1883. On the other hand, some one may object that this is all "as old as the hills," and utilized by every one. It ought to be; but I distinctly doubt if it is. I have never found any one who had habitually employed it.

Let us pass now to the third test of v. Graefe—that with vertical diplopia and prisms. It is, perhaps, in fashion to scoff at this test—never, surely, among those who know how to use it. It furnishes us with just what we want to know—the *habitual* relation between accommodation and convergence. Of course, this relation is not a fixed one; within the limits of the region of relative accommodation and convergence it may by effort be greatly altered; but the habit for each individual is fairly fixed, as we

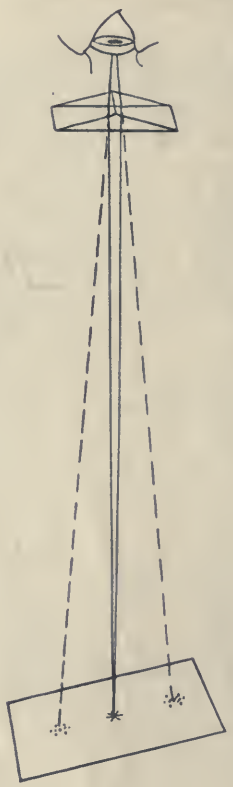
[1] Read before the American Ophthalmological Society, July 17, 1889.

often realize to our cost, if we try to secure abruptly too marked a change in ordering spherical glasses.

Let the underlying principles be clearly realized in practice, and the test will give results that can be relied upon. First, the fixation-object must be such as to hold the accommodation fixed—it must not, therefore, be a huge dot and line that could be seen many yards away, but a fine object, such as an asterisk, or a few letters of Jaeger No. 1, or still finer type. Second, the vertical diplopia must be absolute—no long vertical must be afforded which may be common to both images. In this matter too many have followed v. Graefe's original paper, where this was not fully realized, and too large a test object was there given—to be grossly exaggerated by some of his followers. I have seen titanic "dot and line" figures that occupied the greater part of an octavo page. No eye with a self-respecting accommodation could focus for such an object.

Given a suitable fixation-object and a vertically placed prism (one of 6° or 8° is quite strong enough) and there will be found few cases of lacking balance which will not reveal themselves to this test. In the measurement in degrees of the discovered deviation the revolving prisms of Crêtes will prove a great saver of time and trouble. Using this and a fixation-object which allows of no overlapping of the images, we will rarely be troubled by any question of "latent insufficiency." Perhaps I am confessing to great incapacity as an observer when I state that I have never seen a case of what Dr. E. G. Loring described as latent insufficiency, and of which Dr. H. D. Noyes spoke last year in the Washington meeting. I have met suggestions of it, which promptly yielded to more careful testing. There may be no question as to the possibility of its occurrence, so long as a patient has any region of relative accommodation and convergence; but, as a clinical fact, I have found it in no single case among hundreds carefully tested as to the muscular condition.

A device of extreme utility in using this vertical diplopia test for far or near was suggested some three years ago by E. E. Maddox (*Journal of Anatomy and Physiology*, xxi.), and it has been a surprise to me that so few seem to have noticed it in his abstract in the *Ophthalmic Review* for December, 1886. I have used it with the greatest satisfaction since seeing his paper. It consists of an obtuse-angled prism—or, as it may be otherwise stated—of a double prism base to base. It is held with the junction line of its two inclined surfaces bisecting the pupil, and gives, of course, two false images equidistant from the true position of the object.[1] In practical testing for distance the observer can cover one eye with the hand which holds the red glass, while he brings the prism into position with the other. A double point of light near the pole of the cornea tells when this is accomplished, and the patient can at once see two lights, and tell whether they stand in a vertical line. The red glass is then brought in front of the other eye, and a third light is seen tinged red. If midway between the two white lights, and in the same vertical line, every form of heterophoria is excluded at a single blow. On the other hand, the slightest vertical or lateral deviation is at once manifest; the red image may approach or blend with one of the white ones, or may wander to the side. If the strength of the prism is such as to give 1.5° of actual deviation in each direction—say 3° of angle in the older notation—no normal muscles are able to blend the real image with one of those vertically displaced; at 6 m. the apparent displacement is



about 15 cm. above and below the actual level. Only an eye with weakness of inferior or superior recti will see the red image at any notable distance from the proper level, and the deviation may be at once measured with the prisms as usual. Of course, it is well to check the results by changing the double prism to the other eye. The test is as readily applied near by, the fixation-object being an asterisk, or something of the sort, instead of a point of light. The prism is small, and may be conveniently carried

[1] Is not this an easy way of obtaining the double images in ophthalmometers like that of Javal and Schiötz? I have not yet put into execution my intention of testing it.

in the pocketbook, as mine has been for years, always ready for tests at the bedside, as well as elsewhere.

One point, as to the results of my testing, I would like to put upon record here; it has been previously set forth, but not with sufficient clearness: insufficiency of convergence for the near is met in a very large proportion of the eyes tested. Among 81 medical students it was noted (in degrees varying from 2°–12°) in 42 cases, or 52 per cent. Among the last 200 patients on my private case-book (excluding strabismus and presbyopia), there were 154 cases of insufficiency of convergence, 61 of no deviation, 21 of excessive convergence, and 4 of vertical deviation. All of those with inward tendency of the axes were hypermetropes, as were also most of those with deficient convergence.

The tests of the power of the muscles to overcome prisms for distance have not been often of practical value in my hands. Abduction in nineteen cases out of twenty has been from 6°–8°, adduction almost anything which the patient persistence of the examiner choose to make it. I find that most intelligent patients can overcome from 16°–60° abducent prisms, and those who have by the balance-test an unmistakable lack of convergence are sometimes the best at adduction experiments. For myself, with 3°. of outward deviation for distance and 8° at 25 cm., the abduction is 7° and the adduction from 50°–70°; and this not strictly as the result of practice, although I have always been able to converge my eyes enormously at will, for when first tested by Dr. Risley, ten years ago, the results were almost identical. My refraction is low H., and my accommodation normal.

The point on which I wish to lay stress is, that insufficiency of convergence for the near is the rule among hypermetropes. The reason seems not far to seek. The hypermetrope can avoid excessive convergence only by utilizing and developing the negative part of his range of relative convergence; and, like many of nature's compensations, the correction is overdone. Excessive convergence gives place to deficient convergence. Of course, I am speaking of uncorrected hypermetropia; the convex correcting glasses will give relative divergence in all but the actual squint cases, but these are the cases where the demand for excessive accommodation is still present.

As for the other side of the scale—the inward tendency of the visual axes—I have met hardly a case which could be considered one of insufficiency of the externi. A few cases of actual paresis and a number of the concomitant converging strabismus of hypermetropes, are the only apparent instances of the condition which have presented themselves.

HOSPITAL NOTES.

JEFFERSON COLLEGE HOSPITAL.

Clinic of J. M. Da Costa, M.D.

PHLEBITIS FOLLOWING TYPHOID FEVER—THREE CASES.

(Reported by E. P. Hershey, M.D., Clinical Assistant.)

Case I.—*October 18.* P. H., æt. twenty, laborer. Had typhoid fever ten weeks ago, lasting five weeks. During the third week of the fever, the left thigh began to swell and became very painful. In two weeks the swelling reached the knee, leg, and ankle of the same side. The leg is still swollen, though the swelling in the thigh has disappeared. When he first walked he experienced pain in the left thigh which has since disappeared. Heart very much overacting; a soft murmur may be heard at the base. The pulse is quick and compressible. There is no enlargement of the saphena. No pain in the calf of the leg on pressure. Urine amber, acid; sp. gr. 1020. No albumin; no sugar.

Case II.—C. S., æt. twenty-three, mechanic. Last July had typhoid fever; during the third week the left thigh began to swell; pain was felt along the saphenous vein. The thigh and leg are still swollen to a considerable extent—the whole leg from the crest of the ilium down to the foot. The internal saphenous vein is felt as a tense cord. Around the calf the tissues are brawny and hard, but there is no tenderness; it was tender, however, until three weeks ago. The veins can be felt, though they are not perceptible to the eye. Heart fairly well acting; there is a distinct second sound. There is no murmur at either base. The tongue is slightly coated. The appetite and digestion are good. There is no pain in the leg unless he walks a good distance, and then it begins to swell up more. Urine amber; acid, sp. gr. 1020. No albumin; no sugar.

Case III.—A. K., æt. twenty-nine, blacksmith. Had typhoid fever two months ago. During the third week of the fever, the left thigh began to swell, with but little pain. The swelling is marked when he walks any distance. On pressing deeply the saphenous vein may be felt swollen and tense, and is tender. The tissues about the calf are brawny. The veins are not visible. There is a large quantity of albumin in the urine, which has a sp. gr. of 1012, amber in color and acid in reaction.

Remarks.—These cases all represent the rule of the affection not coming on early in the fever. Even the third week is early; as a rule, they do not appear until convalescence. Here we have three cases where the appearance was during the third week, and as far as we can make out about the same day. All had pain at the time of occurrence. In the first case the pain has entirely disappeared. In the third there is pain on exertion, and in the second the same as the third, except it is more severe. None have pain without exertion.

In the first case only the ankle and leg are swollen; the swelling in the second and third, however, involves the whole leg. In the last two the saphenous vein is tense and swollen; not so, however, in the first case; it is fair to assume that the first case has passed through the same conditions.

Nearly all cases, under proper treatment, recover; the pathology, therefore, is difficult to get at. They are most likely caused by a phlebitis with a thrombus.

As a rule, one leg alone is affected, and, too, what is curious, it is generally the left. Here we have three cases presented at the same time in all of whom the affection is in the left leg. No accurate explanation of this selection has yet been given.

The swelling generally subsides slowly. Exertion generally redevelops the swelling, rather increases the swelling and redevelops pain. Some cases are extremely chronic, and a long time elapses before recovery takes place. One case now in mind, occurring in a business man, still shows swelling upon exertion after three years. In another, in a young man, the swelling develops now, after a number of years, when dancing.

The three cases presented are very instructive. There is no heart lesion. In the first case the overacting heart is due to the state of the blood. In none of these cases is there anything to lead us to suppose that a portion of the plug has been washed off and carried into the heart.

Albumin occurring in the urine of the third case is remarkable, yet explainable. The veins of the kidneys are engorged, caused by plugging of the saphenous vein, hence the albuminuria. This is unusual.

One of the earliest manifestations of this disease recurring in typhoid fever, and one important to bear in mind, is that pressure upon the calf of the leg develops pain; one side is more tender than the other.

The most important factor in the treatment is to keep the patients off their feet. Their business may prevent this, but when they are at home they should sit with the leg up, and thus aid the flow of blood by gravity. Another excellent method is by massage and shampooing. Very active massage is to be condemned; the plug may be broken off. With gentle massage, rub the leg thoroughly, night and morning, with the following liniment:

℞.—Chloral . . . . . ℥j.
Liniment sapon. . . . . ℥vij.

Another very useful plan of treatment is to use hot and cold douches followed by good friction, rubbing in an upward direction. Care should be used not to use any violence. Use bandage when walking or standing.

For the albuminuria in the third case:

Mistur. Basham. . . . . ℥j t. d.

For overacting heart in the second case:

℞.—Tinct. strophant. . . . . gtt. iij.
Tinct. cinchon. comp. . . . ℥j.
Sig. t. d.

There was marked improvement in all of these cases when seen two weeks after treatment.

MEDICAL PROGRESS.

Antacids in Dyspepsia and Gravel.—Sir William Roberts, in opening the Therapeutic Section of the British Medical Association, said that there were few simpler problems than those relating to the palliative treatment of acid dyspepsia and the chemical prophylaxis of uric acid gravel, but there were some practical points in carrying out the treatment which were neither simple nor well known. Antacid agents might be classified into those which were designed to take effect in the stomach, or gastric antacids; and those which were designed to take effect in the kidneys, or renal antacids. The gastric antacids in common use consisted of the alkaline and earthy carbonates and lime-water. Renal antacids combined, in addition to these, the acetates and citrates of potash and soda, which were changed in the *primæ viæ* into carbonates of these bases.

Gastric antacids were employed in two distinct classes of cases—namely, in acid dyspepsia, and in a variety of conditions characterized by great irritation of the stomach, often with vomiting, which we sought to allay by the administration of milk mixed with lime-water. For acid dyspepsia the lozenge was the best mode of administration of an antacid. The Pharmacopœia had two lozenges of this kind, the troch. sod. bicarb. and the troch. bismuthi. The latter was to be preferred. It owed its antacid properties to the chalk and magnesia which it contained, the bismuth being probably inert. Many lozenges sold in the shops contained pungent spices which were injurious. The Tichy lozenges were valuable, but rather costly. It was well to vary the antacid from time to time.

The question might now be put, Is there any harm in the practice of habitually using antacids for the relief of acid dyspepsia? He had naturally at one time regarded the practice with misgivings, but a more extended experience had led him to believe that it was harmless. He used the bismuth lozenge largely, but with the following precautions. They were not to be used at or near meal-times; they were not to be used regularly or systematically, but only when gastric pain was present and produced real discomfort; lastly, the use of the lozenge was to be discontinued if it failed to cut short the pain. Lime-water and milk was a favorite remedy, and often very successful. It sometimes failed, owing to the very low saturating power of lime-water. It was often desirable to substitute a solution of from five to ten grains of bicarbonate of soda per ounce for the lime-water.

The use of renal antacids rested on an equally rational basis. To prevent uric acid gravel forming we had only to keep the urine alkaline; but, simple as this was, there were some practical difficulties in the way, owing to the persistence of the tendency to the uric acid formation. It was very important to remember that this tendency did not last throughout the entire twenty-four hours, the necessary conditions being only present during the hours of sleep. It followed that if we safeguard the night, the day might generally be left to take care of itself. In the milder cases a full dose of the alkalizing agent at bedtime was sufficient. The citrate of potash was the best preparation. The dose for an adult should not be less than from forty to sixty grains, dissolved in three or four ounces of water. In severer cases a second dose should be taken about the middle period of the hours of sleep. In still more severe cases additional doses might be required, but usually only temporarily. The essential point in the prophylactic treatment of uric acid was to guard the urine from precipitating within the precincts of the kidney. An antacid which was too feeble to render the urine actually alkaline might postpone the time of precipitation.—*Lancet*, Aug. 17, 1889.

Fissures of the Tongue.—Great difficulty is generally experienced in the treatment of fissures of the tongue,

and the unpleasant malady seems, at times, to defy all therapeutic measures. Dr. Schwimmer, in the *Journal de Méd. de Paris* of August 4th, recommends the following, the use of which he has observed to be followed by the most marked success:

℞.—Papayotine or papaine . . 1 part.
Glycerine } . . . āā 10 parts.—M.
Water }

After drying the parts, apply the mixture several times daily.

Alcohol in Puerperal Fever.—At the meeting of the German Society of Obstetrics and Gynecology which was held on the 28th of June, Dr. A. Martin read a paper on the efficacy of alcohol in puerperal fever. Eighteen cases were cited, five of which died. Three cases were of pyæmia and fifteen of septicæmia. Besides the alcohol treatment, a strict local antiseptic treatment was also resorted to. The alcohol was given in large quantities in the shape of various wines and spirits together with a most nutritious diet. One of the cases which recovered was given, inside of six weeks, 17 bottles of cognac, 13 bottles of burgundy, 37 half-bottles of champagne, 4½ bottles of other heavy wines, and 6 bottles of porter. When slight diarrhœa was observed the wine was changed.—*Deutsche med. Wochenschrift*, July 25, 1889.

Tannin Injections in Typhoid.—Since the excellent results obtained by Cantani in the treatment of typhoid with enemas of tannin solution, the method has also been tested by several physicians in Germany; foremost among these are Dr. Mosler (*Münchener med. Wochenschrift*, July 23d) and Dr. Backhaus (*Deutsche med. Wochenschrift*, No. 29). The results obtained by these investigators are equally as good as those of Cantani. Mosler's method of using the remedy is as follows: He gives two injections daily of thirty grains of tannin in two quarts of water at body temperature. Later he increases the amount of tannin to nearly three drachms, the same amount of water being used. The enemas should be given slowly so that any sudden distention of the bowel be avoided. In all cases great relief was experienced after the use of the treatment, the diarrhœa disappearing entirely. The temperature is not affected by the use of the drug.

Salve for Anal Fissures.—The following salve, given in the *Revue gén. de Clin. et de Thérap.*, is designed to augment the healing in conjunction with the use of other curative methods. The fissures should be thoroughly stimulated with nitrate of silver and the salve applied several times daily. Its antiseptic and analgesic properties will be found most valuable.

℞.—Boracic acid . . . . 3 parts.
Hydrochlorate of cocaine . 1 part.
Lanolin . . . . . 30 parts.—M.

Radical Operation for Varicocele.—A simplification of the operation for the radical cure of varicocele has, of late, been extensively discussed among French specialists. Lucas Championnière and Reclus, in the *Ann. des Malad. des Organ. génito-urin.*, No. 4, 1889, and Paul Segond, in the *Centralblatt für Chirurgie* of August 10th, state that from extensive experience they maintain that the result obtained by mere resection of the scrotum is equally as good and certain as that obtained by operating directly upon the enlarged veins themselves. The former operation is devoid of danger, excepting that which is incurred by any surgical procedure, and also most simple. The latter, or old radical operation, is occasionally attended by complications far from pleasant.

Tillaux, in writing on this subject in the *Tribune Méd.*, No. 7, 1889, forwards the opinion that the spermatic artery is of but slight importance to the nourishment of the testicles, and has frequently sacrificed it when resecting the anterior plexus of veins, in the operation of varicocele of the spermatic veins. The place of the spermatic artery is readily taken by the deferential artery, which should remain undisturbed when the vas deferens is isolated.

Horteloup, although advocating resection of the skin of the scrotum, in doing this also removed the posterior bundle of veins; other operators have, however, proved that mere resection of the skin is equally as efficacious.

In the operation the testicles are pushed up as high as possible, and the scrotum below caught with a clamp, such as is used in securing the pedicle in ovarian operations or circumcision, then a row of silk sutures passed through the scrotum above the clamp, and temporarily held in place with artery forceps; then the part of the scrotum below these ligatures is resected away and the sutures knotted.

Sycosis Vulgaris.—Dr. O. Rosenthal, in the *Fortschritte der Med.*, August 1st, claims that the etiology of sycosis is still very uncertain. Efficient therapeusis he has nevertheless found. He substitutes for the former painful methods of treatment, the use of the following salve, which, it is claimed, acts almost like a specific:

℞.—Tannic acid . . . . . ℥jss.
Lactate of sulphur . . . ℥iij.
White oxide of zinc } . . āā ℥jvss.
Amyl }
Vaseline . . . . . ℥jss.—M.

The following modification will be found equally valuable:

℞.—Tannic acid . . . . . 15 grs.
Lactate of sulphur . . . 30 "
Vaseline . . . . . ℥v.—M.

Infantile Hysteria.—Drs. Hagenbach-Burckardt and Duboisin agree with the view of Liebermeister, viz., that hysteria is a functional pathological condition of the gray substance of the brain, and must, therefore, be regarded as a psychical disease, and not a neurosis. They also claim that psychical symptoms are never absent; indeed, in some cases, they are the only existing ones. The type of hysteria occurring in children is usually most simple, and, therefore, such cases are especially adapted for the study of the disease. Burckardt and Duboisin have carefully studied the history of twenty-four cases of infantile hysteria, in which predisposition played an important part. They found that in fifty-eight per cent. of the cases a hereditary neuropathic tendency could be traced, whilst fifty per cent. of the cases inherited tuberculosis. Only three cases, in which the disease was but slight, were free from both the above-named predis-

positions. All the patients, with two exceptions, were anæmic. Two had previously suffered from poliomyelitis anterior acuta. In eight cases only was the initiative cause traced to fear, shock, etc. But few instances of ultimate cure were observed. The majority remained anæmic, and continued to be troubled with either headache, palpitation, nervousness, bodily and mental weakness, weak-mindedness, or hysterical psychosis. The prognosis may, therefore, be regarded as unfavorable. This, however, is largely dependent upon early diagnosis and treatment. —*Centralbl. für klin. Med.*, August 3, 1889.

Treatment of Hemorrhoids.—Some time since Unna strongly recommended the use of chrysarobin in hemorrhoids. A report of twenty-two cases treated with this remedy now comes from a Russian physician, DR. KOSSOBUDSKI. True, he did not use the drug in such strong solutions as recommended by Unna (five to ten per cent.), yet the result of the treatment was most gratifying. After washing the parts with a two per cent. carbolic acid, or a one per cent. creolin solution, and drying them with absorbent cotton, he applied, three or four times daily, a salve of the following formula:

℞.—Chrysarobin . . . grs. xij.
Iodoform . . . . grs. v.
Extract of belladonna . . grs. jx.
Vaseline . . . . ʒjv.—M.

In cases of internal hemorrhoids he prescribed suppositories as follows:

℞.—Chrysarobin . . . . grs. 1¼.
Iodoform . . . . gr. ⅓.
Extract of belladonna . . gr. ⅙.
Cacao butter . . . grs. xxx.
Glycerine q. s. for suppository.

If bleeding was severe, tannin was added to the above. With such therapeusis the pain and bleeding disappeared in all cases within three or four days, and the hemorrhoids had completely shrunk away in three or four months.—*Centralbl. für Chirurg.*, August 17, 1889.

The Treatment of Placenta Prævia.—DR. BRAXTON HICKS recommends (*Lancet*, Aug. 17, 1889) the following method: 1. After the diagnosis of placenta prævia is made, proceed as early as possible to terminate pregnancy. 2. When once we have commenced to act, we are to remain by our patient. 3. If the os is freely expanded and the placenta marginal, rupture the membranes, and wait to see if the head is soon pushed by the pains into the os. 4. If there be any slowness or hesitation in this respect, employ forceps or version. 5. If the os is small and the placenta more or less over it, carefully detach the placenta from round the os, and if no further bleeding occurs we may wait an hour or two; but should the os not expand, and if dilating bags are at hand, the os may be dilated. If it appears that the forceps can be admitted easily, they may be used; but if not, version by the combined internal and external method should be employed, and the os plugged by the leg or breech of the fœtus; after this is done, the case may be left to nature, with gentle assistance, as in footling and breech cases. 6. If the os is small, and if we have neither forceps nor dilating bags, then combined version should be resorted to, leaving the rest to nature, gently assisted. 7. If during any of the above manœuvres sharp bleeding should come on, it is best to turn by the combined method in order to plug by breech. 8. When the fœtus is dead, or labor occurs before the end of the seventh month, version by the combined method, no force following, is the best plan. To these Dr. Braxton Hicks added, if we employ a routine method in most cases, it will be found that version by the combined method, no force following, gives a result as good as, if not better than, any. As to after-treatment, act on modern principles. Should oozing occur after expulsion of the placenta, swab the lower uterus by styptics, and irrigate the uterus daily with some antiseptic solution, and particularly, if irrigation cannot be done, insert iodoform pessaries in the vagina. This is especially useful if the outlet of the uterus is blocked by adherent clots.

Formulæ for Infantile Constipation.—We quote the following from the *Lyon Méd.* of August 4th: For constipation in newborn infants, DRS. WIDERHOFFER and MONTI prefer mannite to any other drug. Its action, whilst mild and non-irritating, is also efficient. The formula usually employed is:

℞.—Crystals of mannite . . . 5 parts.
Water . . . . . 50 " —M.

Dose, one teaspoonful, given every two hours.

Another favorite formula is that of DR. WIETHE, of Vienna, it reads as follows:

℞.—Powdered rhubarb root } āā grs. xlviij to lxxx.
Carbonate of magnesia }
Oleo-saccharure of fennel or anise, grs. xlviij.—M.

The dose is said to be "a pinch" of the powder three times daily.

Hemorrhage from the Umbilical Cord.—DR. AUVARD has recently described an instructive case of this accident, which occurred six hours after birth in a private case. The cord was carefully tied one inch and a half from the umbilicus; it was thick and contained much Whartonian jelly. Four hours later, Dr. Auvard visited the mother, who was thirty-five years old, and had borne two other children. Looking at the infant he noticed that it was rather pale, but sleeping comfortably. He was sent for an hour and a half later, as the nurse had found the child's binder soaked with blood, and its extremities were cold. The cord was immediately tied again, and the child kept warm. On Dr. Auvard's arrival he found that drops of blood kept issuing from the stump of the cord, notwithstanding the new ligature. He tied the three umbilical vessels separately; the hemorrhage then ceased, and the infant, a well-nourished female, recovered perfectly.—*British Medical Journal*, August 10, 1889.

Injections of Salt and Water after severe Hemorrhage.—The following case is reported in the *Centralblatt für Chirurgie* of August 3d, by DR. PREGALDINO:

The patient, a woman, aged thirty-eight, had lost an enormous quantity of blood after an abortion. When called in, Pregaldino found her unconscious and pulseless, heart tones almost inaudible, respirations merely superficial. He immediately lowered the head and raised the body, wrapped an elastic bandage around the

lower extremities, and tamponaded the vagina. Finding that the patient continued to sink, he injected seven fluidrachms of a five per mil. solution of salt and boiled water, under strict antiseptic precautions, under the skin of the abdomen. He injected three and a half fluidounces at the same point and three others, inside of twenty minutes. During the injections massage was applied to the abdomen. Consciousness soon returned, and the patient raised herself. After this an additional seventeen fluidounces of the solution were injected. The result was speedy recovery.

Oxygenized Water in the Treatment of Blennorrhagia.—We quote the following formula from the *Journal de Méd. de Paris* of July 28th:

℞.—Oxygenized water (10 per cent. solution) . . . . f℥j.
Distilled water . . . f℥j.
Bichloride of mercury . . gr. ¼.—M.

Three injections should be made daily; the treatment need only be continued for two or three days.

Lime as a Disinfectant.—A short time ago the results of a number of experiments regarding the germicidal properties of lime, were published by Kitasato, Liborius, and Pfuhl. These investigators tested principally the antibacillary properties exerted by lime in feces containing cholera and typhoid germs. These results were indeed most happy and proved the powerful germicidal properties of lime even in proportions of 4 to 1000.

Quite recently (*Arch. de Méd. et de Pharm. militaire*, August, 1889) the results obtained in Germany have been confirmed by DRS. RICHARD and CHANTEMESSE, of Paris, who also quote the experiences of other investigators which coincide with their own. For disinfecting purposes they used a 20 per cent. solution of lime, or "lait de chaux" as it is termed by them. Comparative tables given, show that in the feces of typhoid and dysentery the germicidal efficacy of lime is far greater than that of sublimate solution (1 to 1000), hydrochloric acid (5 to 1000), or chloride of lime (5 per cent.).

Creolin in Dysentery.—Our readers will remember our having cited in THE MEDICAL NEWS of July 20th, the happy results obtained by a Russian physician with creolin injections in dysentery. The *Lancet* of August 3d now reports that another Russian physician, DR. KOLOKOLOFF, has also employed one per cent. creolin injections in this disease in a number of cases with complete success. In the majority of cases two or three injections effected a cure. No unpleasant symptoms seem to follow their use.

Homerania in Tuberculosis.—Homerania is a plant belonging to the polygonaceæ, and has been successfully employed by DR. LASKOFT in the treatment of tuberculosis. The plant is indigenous to Russia, and an irritant oil is extracted from it. Laskoft prescribes an infusion or decoction of the plant in many respiratory affections, particularly bronchitis and tuberculosis. He states, in the *Journal de Méd. de Paris* of August 4th, that he has treated 112 cases of tuberculosis with this remedy, and in 90 cases complete cure was effected. In the early stages of the disease the improvement of the system in general was most marked, together with a steady regression of the pulmonary lesions, which could be determined by auscultation and percussion. In the advanced stages of the disease cure was not effected by the drug, although the general condition of the patient was greatly ameliorated by its use. The night-sweats ceased, and the cough and expectoration greatly diminished.

Laskoft gives the following formula for the drug:

℞.—Infusion or decoction of homerania f℥j.
Distilled water . . . . Oij.—M.

Sig.—To be taken in twenty-four hours.

Conjugal Diabetes.—At the last meeting of the "Hospital Medical Society" of Paris, reported in the *Revue gén. de Clin. et de Thérap.* of August 1st, DR. DEBOVE reported six instances where diabetes had occurred simultaneously in man and wife. As this coincidence has also been frequently observed by other practitioners, he considered the subject worthy of careful investigation. Debove does not accept the theory that the simultaneous existence of the disease may be due to the defective alimentation of both patients, but, rather, that contagion is seemingly possible, if not probable.

Several members of the Society reported simultaneous or consecutive cases of the disease in their own practices.

Antiseptic Treatment of Variola.—A novel and apparently efficacious method of treating variola has been advanced by DR. LEWENTANER in the *Therap. Monatsheft.* It consists of application to the face of a three per cent. carbolic or salicylic paste, made with starch and oil of sweet almonds. The application is kept on the face by means of a mask. The body and limbs are frequently anointed with the following salve:

℞.—Glycerine (neutral) . . . 70 parts.
Starch . . . . . 30 "
Salicylic acid . . . . 3 "—M.

Internally, Lewentaner gives every quarter or half hour a few drops of the following:

℞.—Oil of sweet almonds . . f℥ss.
Syrup of orange flowers . . f℥jss.
Laurel water . . . . f℥iij.
Hydrochlorate of quinine . . grs. v.
Dissolve in hydrochloric acid q. s. to make emulsion.

In six cases where the treatment was used all recovered without any complications and without scars. The duration of the disease is greatly shortened by the treatment, the average, after the appearance of the eruption, being twelve to thirteen days. There was almost an entire absence of fever during the course of the malady. The contagiousness of the disease seems to be completely suspended by means of the treatment. The patients in question were surrounded by other children, not vaccinated, yet none took the disease.

Nervous Cough.—At the last Meeting of Physicians in Cologne, DR. PAUL KOCH delivered an address on the subject of nervous cough; at the close of which he stated the following conclusions which his researches had caused him to arrive at:

1. The existence of a purely nervous cough cannot be denied, although the term is often misapplied.

2. The diagnosis can only be determined after the perfect soundness of the organs of the chest and abdomen has been confirmed.

3. The pathognomic symptom is a cough of unvarying sameness in the individual affected.

4. The multiplicity of curative measures for this affection is a proof of their inefficiency. The disease usually cures itself. A sea voyage or change of air and scene acts most beneficially.—*Wiener klin. Wochenschr.*, July 25, 1889.

Injection for Leucorrhœa.—We quote the following from the *Union Médical*, August 13th:

℞.—Chlorate of potash . . . 12 parts.
Laudanum . . . . 10 "
Tar water . . . . 300 "—M.

Two or three tablespoonfuls of the mixture, added to a quart of water, should be used as an injection every morning and evening. The duration of each injection should be about five or six minutes. Under this treatment the fetid discharge is said to occur frequently.

Cure for Oxyuris Vermicularis.—According to the *Canada Medical Record* for August, oxyuris vermicularis will promptly disappear after injections, per rectum, of cod-liver oil, pure or made into an emulsion with the yolk of an egg. It is non-irritating, and is said never to have failed in effecting a cure.

Strychnine in Alcoholism.—JAROCHEWSKY, in the *Journal de Méd. de Paris* of July 21st, reports two cases of chronic alcoholism and one of dipsomania which he successfully treated with strychnine. In all cases the region of the stomach and liver was painful to the touch. One case was clearly hereditary. The treatment consisted either in hypodermic injections of $\frac{1}{32}$ gr. of strychnine, repeated in ten days; or daily doses, by the mouth, of $\frac{1}{40}$ gr. of strychnine for two to five months. In every instance the recovery was complete.

Excretion of Phosphates in Rickets.—DR. V. TEDESCHI, of Trieste, publishes in the *Rivista Veneta di Scien. Med.* the following results of his examination of the urine, feces, and sweat of rachitic patients compared with those of healthy people. In the urine of healthy children the phosphates varied in quantity even though the diet remained unchanged, the maximum and minimum amount of phosphates generally following one another directly. The urine of rickety children showed the same variation. The variation was probably the cause of different results in different examinations. As a rule, however, the phosphates in the urine of rachitic children were greater than in healthy children. The phosphates in the feces were increased when the child was constipated, and diminished in diarrhœa. The feces in the diarrhœa of rickety children contained less phosphates than those in the diarrhœa of non-rickety children, except the latter happened to be suffering from intestinal catarrh. Whenever the phosphates were increased in the feces of rachitic children the same increase took place in the urine, and the same may be said of the decrease. The best remedy for the treatment of diarrhœa in rachitis seemed to be phosphate of lime. The profuse secretion of the sweat glands in rachitis contained more saline matter than is usually to be found in the secretion of healthy children.—*The Lancet*, August 17, 1889.

Hydrate of Amylen in Epilepsy.—WILDERMUTH has used one-half to one drachm doses of hydrate of amylen with considerable success in epilepsy. Also in cases where bromides had previously been used in excess. It proved to be valuable in treating several cases of nocturnal enuresis. One and one-half to two drachms of the drug may be given daily. Wildermuth usually prescribes it in a watery solution. During the epileptic attacks hypodermic injections of the drug have been given with marked success. No unpleasant symptoms were observed to follow large doses. Its long-continued use produced continued sleepiness. The anti-epileptic properties of the drug only lasted for six or eight weeks in most cases.—*Deutsche med. Wochenschr.*, August 15, 1889.

The Relative Growth of Organs of the Body.—An interesting investigation has recently been conducted by DR. OPPENHEIMER, and is reported in the *Centralbl. für klin. Med.*, August 17. Oppenheimer bases the results obtained upon 943 autopsies, at which careful measurements were taken. Briefly summarized they are as follows:

1. The weight of the body reaches its highest point sooner in the female than in the male. The bodily weight of the adult man is usually about twenty times that of the infant, whilst that of the adult female is eighteen times that of the infant.

2. The growth of the lungs greatly exceeds that of the body in general.

3. The heart grows nearly in proportion to the body.

4. Similarly the spleen and kidneys.

5. The liver and brain grow relatively slower than the general organism.

Treatment of Diphtheria.—CHANTEMESSE and WIDAL, in the *Prager med. Woch.* of July 31st, speak of the results obtained by them with various antiseptics upon the bacillus of diphtheria. After numerous experiments they settled upon the following formula, which seemed most efficacious and practical:

℞.—Carbolic acid . . . . ʒ 2¾.
Glycerine . . . . . ʒ 6¾.
Camphor . . . . . ʒ 5.—M.

Dissolve with heat; cool and decant. The decanted fluid will be a camphorated phenol-glycerol, which should be applied to the diphtheritic patches once or twice daily, the parts having been previously washed with carbolic solution.

Camphorated Naphthol in Tuberculous Ulcerations.—Camphorated naphthol, in a mixture of one part naphthol and two parts of camphor, forms an oily liquid, and may be easily applied to ulcerations of the skin and mucous membranes. DR. FERNET, in *L'Abeille Médicale* of August 19th, claims to have found it a most valuable application for tuberculous ulcerations, especially those of the mouth and throat. Fernet by no means asserts that in camphorated naphthol to have found a cure for tuberculous ulcerations, but holds that by its use the local symptoms will be greatly ameliorated.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, SEPTEMBER 7, 1889.

RESPONSIBILITY IN THE MANAGEMENT OF CONTAGIOUS OR INFECTIOUS DISEASES.

APART from the legal aspects of the question of compulsory notification of contagious or infectious diseases to the local health authority, the medical practitioner is bound by moral obligation to do all within his power to restrict or prevent the spread of diseases of this class which cause so much suffering and loss of life. The physician, from the close personal relations which he bears to the sick, and the dependence placed on his judgment and advice, possesses exceptional advantages for instituting and directing measures for the protection of the health of the family and of the community, and therefore holds a position of the greatest responsibility. The notification of the local health authority does not relieve him from this responsibility, but, by inviting coöperation, strengthens his hands in the performance of duty.

In the early stages of disease, when doubts arise as to the diagnosis, an invaluable opportunity for instituting protective measures is often lost by awaiting, inactive, the future development of the symptoms. Suspicions of the infectious nature of the disease demand the prompt use of measures of precaution. Epidemics have occurred through the dilatory action of the physician, who, while waiting for distinctive symptoms before employing the means of prophylaxis, has allowed the infection to escape beyond his control. In proof of this statement, a recent epidemic of smallpox arising though such neglect might be mentioned, which involved nearly four hundred cases, eighty of which proved fatal.

The prompt isolation of those suffering from dangerous communicable disease or with symptoms giving rise to suspicions of such disease, the careful attention to ventilation, to personal cleanliness, and to cleanliness of the appartment and everything pertaining thereto, and the employment of rational methods of disinfection during the continuance of the malady and after its termination, and when this termination is by death the proper care of the corpse and the protection of the public by advising against the assembly of persons at the funeral, are all measures of extreme importance which the medical attendant should deem it his duty to enforce. The disregard of his directions is sufficient reason for invoking the coöperation of the health authorities whom the law has clothed with absolute authority in all such cases.

No one is better acquainted than the physician with the value of the scientific use of disinfectants. There is no longer the uncertainty that formerly existed with regard to the methods of employment of these valuable agents. Elaborate and precise investigations conducted in the laboratory with the object of determining the relative potency of various substances in destroying the germs of disease, have yielded definite and valuable results, so that we now have at our command a number of agents of positive efficiency in destroying all known morbific poisons which emanate from the bodies of the sick.

The number of cases of disease of the class we are considering over which the health authorities assume special control is comparatively small; the greater number is left to the care of the medical attendant. The Board of Health may prescribe rules and regulations to be observed in the management of all such cases, and impose penalties for their infraction. It is not possible, however, by official espionage to obtain knowledge of the manner in which these regulations are observed; and hence this information must emanate from the medical attendant, who for the time being is constituted a quasi health officer, upon whom there is imposed a dual obligation, that to the patient and family and that to the community generally. The neglect of this responsible duty from personal considerations is deserving of the severest condemnation. The suppression of the true knowledge of the disease, the allowing of intercourse with the sick, or the attendance at school

of children from an infected house are instances of breach of duty, the consequences of which can readily be foreseen.

The occurrence of disease which from its nature is liable to spread and inflict great injury upon the community, calls for special and immediate action upon the part of the medical attendant. To a certain extent he should act as the guardian of the public health. It is his duty to inform the health authorities promptly of the existence of such disease, and to acquaint himself with the law and regulations pertaining to its management, and to coöperate willingly in carrying out all measures prescribed for restricting the spread of contagion. His peculiar relations to the family enable him to institute and supervise all needful precautions without the annoyance incident to official interference. If these advantages are fully appreciated and turned to practical account, there need be no occasion for intrusion of the authorities. The physician, however, cannot exercise his option in the matter of reporting these cases; the law requires it and must be obeyed. It is reserved for the health officer to judge whether the measures employed meet the necessities of the case. Besides insuring the proper management of individual cases, there are other objects of notification, which are the prompt adoption of general measures of prophylaxis, the investigation of the origin, causes, and course of outbreaks of virulent disease, the collection of statistical data, all of which are greatly facilitated by prompt and accurate report to the proper authorities.

COLORECTOSTOMY.

THAT colorectostomy, or the formation of an anastomosis between the rectum and colon, will gain for itself such popularity over inguinal colotomy as the latter operation has over lumbar colotomy, we do not anticipate. Were inguinal colotomy impossible, we would stop to consider whether in all cases the more serious (if practicable) procedure would not be justifiable, that our patients might be saved from the subsequent filth and discomfort of the lumbar operation, now happily almost a thing of the past. But not so; for, while anterior colotomy has been reduced to an extreme minimum of primary risk and secondary discomfort, and is applicable to all cases, on the other hand, colorectostomy must of necessity be limited to a small class, and be much more difficult and dangerous.

The operation has not, as yet, been performed upon the living body, but, from studies upon the cadaver, is described by its projector, DR. EMERICH ULLMANN, in the *Wiener med. Presse*, No. 24, 1889. Its possible field is limited to highly situated and closely circumscribed disease of the rectum; the stricture or tumor mass must be at least several inches above the anus. These necessary conditions being present, Ullmann proposes to operate as follows:

The rectum having been emptied and cleansed, an incision is begun midway between the left tuber ischii and anus, and carried upward to the same side of the sacro-coccygeal junction, and downward through the levator ani muscle, pelvic fascia, and peritoneum to the full length of incision. Should there not be sufficient room at this or any subsequent stage, the coccyx can be partly disarticulated and turned aside, or at once excised. The rectum and its surroundings are now carefully examined. If excision of the organ is not found to be possible, and the surroundings are not so infiltrated as to prohibit drawing down the colon, operation is continued; otherwise it should be abandoned in favor of excision or colotomy. Conditions being favorable, the thumb and index-finger seek the sigmoid flexure, through the meso-colon of which a strip of gauze is inserted. Traction upon the gauze, with the assistance of the fingers, brings the coil of bowel into the wound. An incision parallel to the bowel axis is then made upon the left side of the rectum midway between the sphincter and stricture. A similar opening is also made upon the right posterior portion of the prolapsed bowel, and the two openings are united in the usual way. The wound of soft parts should be left open, packed, and kept absolutely aseptic.

For one variety of conditions Ullmann's operation may prove of value. That is, in cases of high non-malignant stricture, where the patient otherwise might be compelled to go through a long life with an artificial anus. Here, if our German brethren prove the proposed resource to be surgical, even a considerable amount of risk would be justifiable to gain the result which Ullmann believes quite possible.

THE Director of the Laboratory of the Cronica Medico-Quirurgica of Havana entertained Dr. George M. Sternberg, U. S. Commissioner to investigate yellow fever, at a complimentary banquet on August 24th, prior to his departure from Havana, where he has been for several months studying the bacteriology

of yellow fever. Dr. Sternberg will immediately return to this country and complete his research by an extended comparative investigation, by the same methods, of cadavers from other diseases.

THE Examining Board of the United States Navy, consisting of Medical Director Alfred C. Gorgas, Inspector John H. Clark, and Surgeon Thomas H. Streets, last week held a special session at the Naval Hospital at Brooklyn, for the purpose of examining candidates for eight vacancies in the medical corps.

THE American Public Health Association will hold its seventeenth annual meeting at Brooklyn, N. Y., October 22, 23, 24, and 25, 1889, under the presidency of Dr. Hosmer A. Johnson, of Chicago.

The Executive Committee have selected the following topics for consideration:

I. The causes and prevention of infant mortality.

II. Railway Sanitation. (*a*) Heating and ventilation of railway passenger coaches. (*b*) Water-supply, water-closets, etc. (*c*) Carrying passengers infected with communicable diseases.

III. Steamship Sanitation.

IV. Methods of Scientific Cooking.

V. Yellow Fever. (*a*) The unprotected avenues through which yellow fever is liable to be brought into the United States. (*b*) The sanitary requirements necessary to render a town or city proof against an epidemic of yellow fever. (*c*) The course to be taken by local health authorities upon the outbreak of yellow fever.

VI. The Prevention and Restriction of Tuberculosis in Man.

VII. Methods of Prevention of Diphtheria, with Results of such Methods.

VIII. How Far should Health Authorities be Permitted to Apply Known Preventive Measures for the Control of Diphtheria.

IX. Compulsory Vaccination.

X. Sanitation of Asylums, Prisons, Jails, and other Eleemosynary Institutions.

Papers upon miscellaneous sanitary subjects not included in the above list will be received by the Executive Committee subject to the requirements of the By-Laws.

WE regret to learn of the death of Dr. Thomas King Chambers, Honorary Physician to the Prince of Wales, Senior Consulting Physician to St. Mary's Hospital, and author of "Lectures, Chiefly Clinical," "Indigestions or Diseases of the Digestive Organs Functionally Treated," and "A Manual of Diet and Regimen in Health and Disease," works which were reprinted and widely read in this country. Dr. Chambers was a graduate of the University of Oxford, and was a physician of great culture and marked originality. He died on the 15th ultimo, at the age of seventy-one.

REVIEWS.

LECTURES ON PATHOLOGICAL ANATOMY. By SAMUEL WILKS, M.D., F.R.S., Consulting Physician to, and formerly Lecturer on Medicine and Pathology at, Guy's Hospital; and the late WALTER MOXON, M.D., F.R.C.P., Physician to, and for sometime Lecturer on Pathology at, Guy's Hospital. 8vo., pp. xx., 672. Third edition, thoroughly revised. By SAMUEL WILKS, M.D., LL.D., F.R.S. London and New York: Longmans, Green & Co., 1889.

THE publication of a new edition of a work which has so long enjoyed the high reputation of the Lectures of Wilks and Moxon is not to be wondered at. Owing to the death of Dr. Moxon, shortly before the exhaustion of the former edition, the work of revision has devolved upon his venerable colleague. In this way the general character and scope of the book have been preserved, notwithstanding the introduction of much new matter. To make room for this, without materially increasing the size of the volume, much that was thought superfluous has been omitted, and some of the chapters have been rewritten.

As in the previous editions the subject is treated from the standpoint of the autopsy table rather than from that of the laboratory. Gross appearance accordingly receives more detailed description than histological structure. Throughout the book, also, there is a noticeable deficiency in the discussions of the etiology of the various conditions. This is especially apparent in the notices of the infectious diseases. For example, on p. 430 we read: "It has been said of late that a specific bacillus may be found in typhoid, and the report from Cornil's laboratory is that it has been discovered also in the liver, lungs, and spleen. The difficulty in proving this has been to get a pure cultivation, and to separate the specific form from other bacilli." The etiology of cholera is dismissed with the following (p. 648): "The microbe found by Koch, and which he calls the 'comma-bacillus,' is said to be characteristic. It has been found also by Klein and Gibbes in the dejecta and in the intestine, but they decline to say that it is the cause of the disease."

Inaccuracies are also occasionally noticeable as, on p. 267, where the statement is made that inflammation of a nerve "has been called *peripheral* or *interstitial neuritis*, according as the sheath or the internal structure is affected;" and on p. 167, where we are told that "tubercle is not known to attack bloodvessels." The author himself contradicts the latter statement on p. 181, where he says: "Tubercle is almost unknown in the veins," thus tacitly admitting its occasional occurrence.

It is not with any desire to be hypercritical that these defects are alluded to, but in the hope that they may receive correction in a later edition. None can be more appreciative than we of the usefulness of the book as the embodiment of an experience acquired during years of careful study at the autopsy table.

SOCIETY PROCEEDINGS.

GYNECOLOGICAL SOCIETY OF CHICAGO.

Stated Meeting, March 15, 1889.

THE PRESIDENT, CHARLES T. PARKES, M.D., IN THE CHAIR.

DR. W. W. JAGGARD read some notes on the

ETIOLOGY OF PUERPERAL ECLAMPSIA.

The term denotes epileptiform convulsions, characterized by recurrence of paroxysm after longer or shorter pauses, followed by unconsciousness, that occur during labor, pregnancy, and the puerperium. As thus defined, the expression puerperal eclampsia restricts us to no particular theory as to etiology.

Happily, the symptom, justly regarded as a disease, is of infrequent occurrence. In general terms, eclampsia is observed once in five hundred deliveries. Out of 316 cases collected by Carl Schroeder, convulsions occurred 190 times during labor, 62 times during pregnancy, and 64 times during the puerperium.

Among the modern theories of etiology, the first, as well in point of time as in present importance, is the doctrine that eclampsia is the expression of acute urinemia, conditioned either upon functional or organic disease of the kidneys, or upon obstruction to the flow of urine through the ureters. The evolution of this conception has been gradual, and it may be profitable to trace the stages of its development.

After the recognition of the association of albuminuria and disease of the kidneys with eclampsia by Lever (1842), Jevilliers and Regnault (1848), Frerichs (1851) advanced the hypothesis of uræmia, and suggested that the convulsions were due to the retention in the blood of urea and its decomposition into ammonium carbonate. This notion has become obsolete, since, aside from an isolated observation by Spiegelberg (1870), the presence of ammonium carbonate in the blood in sufficient quantity to cause convulsions has never been demonstrated, notwithstanding numerous examinations of the fluid by responsible chemists. The weak points in the hypothesis of ammonemia have been pointed out particularly by Rouxmelaire, Voit, and Bartels.

The notion of the mere retention of urea, without decomposition-changes, as the cause of the disease, has been shown to be without basis in fact. Winckel has demonstrated that no such accumulation of urea occurs in the most important organs of dead eclamptics—that is, in the liver and muscles—but that, on the contrary, these organs contain less than the normal quantity. E. Voit and M. Stumpf have observed that the elimination of nitrogen through the urine in convalescent eclamptics is about equal to the minimum excreted in the condition of absolute starvation.

Carl Braun, at the same time that Frerichs published his classical treatise (1851), declared puerperal eclampsia to be identical with the convulsions of Bright's disease. Braun's theory (1857) in his own words is: "The interruption of the secretion of urine in both kidneys, the acute retention of all excrementitious matters (normally excreted by the kidneys) in the blood and tissues, exercises a highly pernicious influence and explains the occurrence of eclampsia." In proof of this theorem, Braun has brought forward an amount of evidence that almost amounts to demonstration. Although certain observers affect a disbelief in this etiological doctrine, yet they all fully recognize it in prevention and treatment. Still, Braun's theory, just quoted, cannot be accepted as a universal proposition. It explains the very large majority of cases of eclampsia, but it does not explain all cases.

As originally pointed out by Morgagni (1767), and at a later period by Halberstma (1871) and Löhlein, flexure, infraction, stretching, catarrh, or pressure may prevent the flow of urine through the ureters, and condition, directly or indirectly, urinemia. Although no doubt exists as to the occasional operation of this factor, its etiological moment does not approach the significance of renal insufficiency. Out of thirty-two cases of fatal eclampsia, Löhlein demonstrated dilatation of one or both ureters in eight, or twenty-five per cent. Löhlein concludes that in five of these cases an already insufficient urinary excretion was still further limited, or even entirely interrupted, by retrostasis of urine in consequence of compression of the ureters, so that urinemia and its symptom, eclampsia, followed.

Much light has been thrown within a recent period upon the pathological significance of urinemia. The toxicity of normal urine has been demonstrated, although there is some difference of opinion as to the active agent. Bouchard claims to have isolated five organic poisons, and his observations are supported by Battlehuer, who recognizes the ultimate cause of eclampsia to be a decomposition-product like a ptomaine On the other hand, Voit, Feltz, and Ritter, Astachewsky (1881), Lepine (1885), and Stadthagen (1889) maintain the dominant importance of potash salts, while they admit the effect of the retained nitrogenous matters—urea, uric acid, kreatin, and the like—in the limitation of tissue-metabolism. Closely similar views have been expressed by Nothnagel, Strumpell, v. Jakschk, Fleischer, and Peter.

A plausible explanation of the immediate causation of convulsions in cases of urinemia has been given by Carl Schroeder. The experiments first performed by Kussmaul and Tenner prove that epileptiform convulsions are invariably produced only by ligature of the arteries that supply the brain. It is, accordingly, in a high degree probable that puerperal convulsions are caused by cerebral anæmia. How is this cerebral anæmia effected? The most highly probable view is that of vasomotor spasm of the bloodvessels at the base of the brain. In favor of this view there are the following facts: (1) The inability to explain the cerebral anæmia in any other way; (2) the sudden onset of the convulsions and the rapid *restitutio in integrum;* (3) the negative results of autopsies; (4) the effect of remedies that cause dilatation of the vessels of the brain.

As to the causes of the vasomotor spasm, we have the following facts: (1) The plus state of excitability of the nervous system observed in pregnant, parturient, and

puerperal women as in children, so that a vasomotor spasm will occur, the operation of a cause that at other times would produce no such effect; (2) the vasomotor centre is more irritable, especially during labor; (3) with the predisposition upon the part of the nervous system in general, and of the vasomotor centre in particular, the toxic state of the blood is amply sufficient to give rise to an explosion. What other irritants are at work it is impossible to say. Possibly, as in epilepsy, irritation of the peripheral nerve-endings—that is, irritation of the uterine nerves, or pressure upon the ischiatic nerves—may play a certain *rôle*.

Of uncommon interest are the recent investigations of Stumpf.[1] This observer found that when the expired air of an eclamptic smelled of acetone, that acetone could always be demonstrated in the patient's urine, distilled or not distilled. Knowing the relation of acetone and allied bodies and acetonuria to the coma of diabetics, he at once sought for sugar in the urine of the same individuals, and succeeded in showing its presence in all the cases in which urine in sufficient quantity for testing could be collected. Stumpf came to the conclusion that, under abnormal decomposition-processes, a nitrogen-free, toxic substance—possibly acetone, or an allied body with the same reaction—is developed that during excretion irritates the kidneys to the extent of nephritis, exercises a pernicious influence upon the coloring matter of the blood, and alters the activity of the liver cells so that glycosuria follows; that this action on the liver cells may go on to destruction of the hepatic parenchyma, the production of acute yellow atrophy with the formation of tyrosin and leucin, and, through irritation of the brain, coma and convulsions. Stumpf leaves to the future the determination whether this body is the result of an agent of infection derived from without, or whether it is derived from the fœtus in utero. Winckel is of the opinion that the predisposition to eclampsia in multiple pregnancy, the fatal effect of the eclampsia upon the fœtus, the peculiar rigor mortis of the infants, and, finally, the item that with the death of the child in pregnancy the danger to the mother grows less—that all these facts indicate a close relation between fœtus and mother in the genesis of eclampsia.

Gustav Braun[2] has reported several cases of elampsia in which hemorrhagic hepatitis was the most significant lesion.

Suggestive as the observations of Stumpf and Gustav Braun are, facts are as yet too few to admit of generalization. The importance, however, of more exact analysis of the blood and urine in all cases is obvious.

Passing mention must be made of the Traube-Munk-Rosenstein hypothesis, if for no other reason, because Dr. Freer, of Chicago, some years ago performed certain experiments that led him to broach a similar supposition. Traube's view was that the hydremic state of the blood incident to pregnancy, and increased by the loss of albumin in Bright's disease, constituted the important predisposing factor; that the blood pressure is elevated on account of the heart-hypertrophia of pregnancy; that, under the reflex stimulus of uterine contractions, blood pressure becomes so great as to cause œdema of the middle brain and cerebral cortex, resulting in pressure-anæmia that is followed by coma and convulsions. Rosenstein modified this hypothesis by the omission of the effect of the loss of albumin by the blood. He merely eliminated the nephritis. These notions, as well as the conception of eclampsia as a form of acute epilepsy, at present possess a purely historical interest.

The notion that eclampsia is an example of infection is by no means new. The fact that the disease is always sporadic, never epidemic, renders this hypothesis improbable. But it is quite possible that the Bright's disease may be due in certain cases to infection. Out of five cases recorded by Doléris and Pavey, two were ascribed to an infection nephritis. In these cases it is claimed that the infection of the blood pursued a course parallel with the convulsive seizures. The experiments of E. Blanc,[1] with microbes isolated from the urine of an eclamptic tend to support this view. Inoculations of rabbits with these microbes were followed by convulsions in some cases, and by infection nephritis in others. Upon this phase of the subject, however, Dr. Bayard Holmes has something to say.

About thirty cases of eclampsia have come under the speaker's observation in hospital and private practice. In all of these cases the etiology was perfectly clear. They were all examples of urinemic convulsions, conditioned upon Bright's disease.

(To be continued.)

CORRESPONDENCE.

THE INTERNATIONAL CONGRESS OF THERAPEUTICS.

(From our Special Correspondent)

THE International Congress on Materia Medica and Therapeutics held its first meeting on August 1st, under the presidency of Dr. Moutard Martin; the Congress immediately divided itself into a Section of Therapeutics and a Section of Materia Medica.

In the Section of Therapeutics, the first communication was by Prof. Semmola, of Naples, who spoke on the subject of chromocytometry applied to the indications for mercurial treatment and alterative medication. One of the great difficulties, he said, is to know when to stop the treatment, or, again, when to begin it. This exact measure will be given by making a hemoscopic or hemometric examination of the blood before and during the mercurial treatment; the number of red corpuscles and the proportion of hæmoglobin are always in a constant relation to the biological action of mercury, and this action varies according to its taking place in a syphilitic or in a healthy organism; hence, before a mercurial course is begun, it is important to make a chromocytometric examination of the blood. After the disappearance of the specific symptoms, this same examination is to be repeated every three or four days at least. If the proportion of hæmoglobin increases, the mercury is still indicated; if the proportion diminishes, the patient is cured, and the mercury then acts as a toxic drug. We must always fear that the mercury may act as a destroyer of the blood corpuscles. The

[1] La Semaine Médicale, 1889.

apparatuses which he recommended are the chromocytometer of Bizzozero, the hemochrometer of Malassez, and von Heischl's hematometer. He finally formulated his views as follows: "Chromocytometry must be regarded as giving the exact measure of the indication and use of the drugs which modify the activity of the tissue-changes, because the final and real therapeutic result of this action is unquestionably an increase in number of blood corpuscles, which means an increase of hemoglobin."

M. Cros, of Paris, next made a communication on the mode of action of vesicating substances. He thinks that the vesicating action is a physical one at first. There is produced a dissolution of the vesicating matter in the epidermis, which then behaves itself toward the derm as a real vesicating substance, the physiological action on the derm being secondary.

M. Lavaux, of Paris, read a paper on the "Use of Cocaine in the Treatment of Urinary Diseases." He said that the cocaine solution must not only be placed in contact with the penile portion of the mucous membrane of the urethra but also with the neck of the bladder; in cystitis cocaine is excellent. In few words, the rules of the treatment are: 1st. To anæsthetize at the same time the urethra and the bladder; 2d. To use only a 4 per cent. or even 2 per cent. solution of cocaine, but in sufficient quantity to saturate the vesical mucous membrane. This means the injection of four to six fluid-drachms of such a solution. 3d. This solution is to be injected into the bladder without the use of a sound. The use of cocaine is also to be recommended in spasms of the membranous portion of the urethra, in cystalgia or vesical neuralgia. One fact to be remembered is, that cocaine allows the desire to urinate to remain even if the anæsthesia of the vesico-urethral mucous membrane be complete. This means that it is not the sensibility of the prostatic mucous membrane which plays the principal *rôle* in the desire to urinate, as sustained by MM. Küss and Duval, but that it is vesical distention, as advanced by Prof. Guyon.

MM. Crocq and Lefebvre, of Belgium, would not admit this last physiological deduction, and made the remark that certain patients have a desire to urinate even if there be no fluid in the bladder.

Dr. Guelpa, of Paris, next spoke on the "Treatment of Diphtheria." He said that two of the most important points in the treatment of this disease were to follow a local treatment, and not discontinue this treatment during the night. Antiseptic irrigations and vaporizations are to be resorted to; we must be careful not to apply our treatment too roughly, and guard against wounding the surrounding mucous membrane; for recent investigations have shown that the diphtheritic bacillus can only penetrate the organism through an abraded mucous membrane. Pulverization and irrigation must be made wherever diphtheritic membranes are present; this is the reason why he believes in an early tracheotomy. In cases of nasal diphtheria, the nasal fossæ must be thoroughly cleansed out, and if the disease extends to the maxillary sinus, this cavity must be opened by trephining.

In the afternoon session, Dr. Dujardin-Beaumetz introduced the following subject: "Antithermal Analgesics." He said that this question had been brought before the Congress so as to determine the special action of this class of agents, which are, as is well known, not only analgesic, but also antithermics, and even antiseptics. Some act as antiferments, and combat high temperature by preventing this fermentation; others act on the blood corpuscle, and decrease the temperature by acting on the respiratory power of the blood; while a third class modify the calorific centres of the cord by acting directly on the cerebro-spinal centres; this last class of antithermics possess almost exclusively analgesic power. An important point also is to determine the relation existing between the atomic constitution and the physiological properties of these different medicines. From a series of experiments made by Dr. Dujardin-Beaumetz and Dr. Bardet, the following laws have been obtained, which give an appreciation of the antiseptic, antithermic, and analgesic properties of the new drugs obtained from the aromatic series:

1. The antiseptic effects produced belong especially to the hydrated series (phenols, naphthols, etc.).

2. The antithermic actions are dominant in the amidogenous series (acetanilide, kairine, thalline).

3. Finally, the analgesic properties are found in this last group of amidogenous series, where an atom of a fat radical, and particularly methyl, is substituted by an atom of hydrogen (acetphenetidine, methylacetanilide, dimethyloxyquinizine).

Prof. Lépine, of Lyons, said that even in the healthy animal the antithermic action of these drugs is a complex one; they produce an arrest in the activity of the protoplasms, and most of them act on the red blood-corpuscles by transforming the hemoglobin into methemoglobin, or again attack the tissue itself of the blood corpuscle; but their influence is especially marked on the nervous system. The remarks which he made in 1886, on the nervous action of antipyrine, made him say at that time that all true antipyretics were nerve drugs. This moderating nervous action of antipyrine and the other antithermics is not only an analgesic property, but he has found that under the influence of these agents the quantity of glucose used is diminished in the capillaries; that there is a diminution of the glucose at the expense of the glycogen, in the liver and muscles, and that in certain cases one can even find a diminution in the formation of the muscular and hepatic glycogen. Their action on the quantity of albuminoid used, which depends on the age and dose, is a variable one, and is not to be neglected when considering the production of heat. It is to a diminution in the consumption of hydrocarbons in the economy that we must attribute, for the greater part, the reduction in the temperature observed in small animals. M. Lépine concluded by saying that these agents are poisonous to the protoplasm, but much less active than quinine; their principal action being on the nervous system, they modify certain sensitive impressions and, at the same time, the production of heat, by preventing the too great use of hydrocarbon materials.

M. Masius, of Liege, said he preferred the use of phenacetine in the treatment of tuberculosis and typhoid fever, as well as in the different forms of rheumatism. As an antineuralgic, he uses this drug by giving it in doses of from fifteen to forty-five grains, its action is less dangerous than antipyrine. In animals, phenacetine, given in toxic dose, brings on death by asphyxia, while in smaller doses it will produce motor and sensory paralysis.

Dr. Francis H. Williams, of Boston, did not believe in the use of analgesics during fever; he said that they produce only a temporary relief; but, on the other hand, their

use prolongs the appearance of convalescence. Again, in certain cases, their use may be accompanied by danger —these facts are sustained by Dr. Stokvis, of Amsterdam.

Dr. Desplats, of Lille, had used antithermics for more than ten years, and finds constant satisfactory results: the temperature falls, secretions are more profuse, and the patient feels much better; but their action being of a temporary character, they must be continuously administered.

M. Snyers, of Liege, had made comparative studies of the different analgesics in regard to the symptoms produced by kairine, antipyrine, thalline, acetanilide, and phenacetine, and he has found that antipyrine was by far the safest to be used.

Dr. Bardet, of Paris, next spoke on the use of the new analgesic, methylacetanilide, known as exalgine; he finds it a powerful analgesic, in all neuralgias due to cold or congestion. Out of 75 cases observed, he finds that in 10 cases of rheumatism the pain completely or almost completely disappeared, in 5 cases doubtful result, in 3 no result at all; in 3 cases of cardialgia, good results; in 14 cases of neuralgia, rapid results; in 13 cases, certain results but less rapid; in 5 cases, negative results—they were cases of chronic sciatica.

Dr. Dujardin-Beaumetz, as well as M. Bucquoy, did not think exalgine as reliable as antipyrine; it has a greater tendency to bring on cyanosis and vertigo, which appear whenever the dose of the drug reaches 7½ grains.

Next came the discussion on the second question which had been placed before the Congress, "On Cardiac Tonics." M. Bucquoy opened the subject, by saying that in cardiac therapeutics our aim is not so much to combat the lesions of the organ as to sustain its action. For a long time digitalis has been the principal agent, and it is one that must not be disregarded to-day, although many other drugs have been recommended instead, such as convallaria maïalis, adonis vernalis, strophanthus, and squill. Most of them act by increasing the systoles of the heart, and especially the ventricular systole, making the pulse regular by increasing the arterial tension and producing a more or less abundant diuresis; it would be well, however, to know what is their action on the vaso-motor system, for they are not all vaso-constrictors as digitalis; it would be also useful to ascertain how long they can be administered without danger of accumulation. It is also necessary to know whether the alkaloid, the active principle of the plant, can be prescribed like the plant itself and if the effects produced are the same.

M. Masius, of Belgium, preferred to administer digitalis in powder for a heart tonic, while Dr. Dujardin-Beaumetz gave preference to the infusion of digitalis.

M. Bucquoy gave an account of 206 observations which he had made with strophanthus. Under the influence of strophanthus the pulse becomes slower and more regular; it takes the character of the aortic pulse, even in pure mitral patients. When in a mitral patient the pulse becomes aortic under the influence of the drug, when the pulse, which was primarily feeble, becomes able to arise high the sphygmographic needle, and give ascending lines equal to the normal rather than to the aortic pulse, we can say that we have to deal with a "strophanthic pulse." In mitral patients the pulse becomes aortic, while in aortic cases the pulse of Corrigan is exaggerated. M. Bucquoy thinks strophanthus is a very safe drug and capable of being given for an indefinite time; in regard to diuresis, it has a constant action. Its action will be useless if the cardiac muscle is degenerated.

M. Féréol prefers the infusion of digitalis, yet recommends the use of digitaline as advised by Prof. Potain, in large doses; one dose being sufficient for eight or ten days.

Prof. Semmola, of Naples, also prefers digitaline.

M. Crocq, of Brussels, read a communication on the "Treatment of Pneumonia by Acetate of Lead." He first remarked that pneumonia is not a disease that runs a very regular course; some cases present a defervescence of the fever on the seventh day, while others will go on much longer—several weeks. He said that at present pneumonia often passes into chronic pneumonia on account of our expectant plan of treatment, instead of favoring the absorption of the pneumonic exudate. He thinks acetate of lead is most efficacious to prevent a pneumonia from becoming chronic. In Germany this drug was formerly recommended by Nothnagel and Rossbach. Leudet has used it in France. By means of this treatment the speaker has observed that the number of pulsations are greatly reduced, the elevation of temperature comes down rapidly, and the sputa disappear. Sometimes he associates laudanum with the acetate of lead to prevent diarrhœa. He recommends a minimum dose of six grains, while up to fifteen grains can be given to an adult in twenty-four hours; the treatment can be continued without danger from twelve to fifteen days. In cases of pneumonia in a healthy, vigorous subject he prefers bloodletting; but in all pneumonias of the weak, of alcoholics, of diabetics, it gives marvellous results.

Prof. Semmola, of Naples, next read a paper on the "Use of Continuous Electric Currents in Chronic Lead-poisoning." He claimed that this method stimulates the nutritive process, and favors the elimination of the lead by the different excretory organs; a very few days after beginning the treatment it becomes possible to find lead in the urine, and this elimination continues as long as the treatment is kept up; the lead gum-line gradually fades away; the atrophied muscles become more active, and he had even seen old paralysis of the extensors disappear under this treatment; formerly he only placed the negative pole in simple communication with the bath, and the positive pole on the patient; now he places one pole on the neck, the other on the vertebral column. By these means he has obtained twelve complete cures of lead-poisoned patients who had been placed in an incurable hospital. This treatment seems to be of no avail when the patient has presented signs of encephalopathy.

M. Constantin Paul said he had never been able to find lead in the urine of his saturnine patients who were treated by electricity, unless iodide of potassium was given at the same time.

Prof. Semmola said he never gave iodide of potassium in any of his cases.

M. Pétrescu, of Bucharest, read a paper on the hyperemetic action of digitalis, and its antiphlogistic action on pneumonia; his conclusions are that pneumonia can be aborted, if treated early enough, by large doses of digitalis; this treatment of pneumonia is the most rational one, being based on its pathogenic indication; the efficacy of this treatment is also confirmed by statistics; the lowest mortality is found in cases of pneumonia treated

by large doses of digitalis. One to two drachms of the leaves of digitalis given in an infusion is the real therapeutical dose for a pneumonia of adults. The tolerance and non-toxic effect of this therapeutic dose are given in his work, made after a series of 757 observations.

Prof. Semmola is somewhat sceptical about giving such formidable doses of digitalis without dangerous effects being produced.

M. Bucquoy examined the tracings of the patients of M. Pétrescu, before and after treatment, and he found that all but one presented tracings of intoxication.

M. Constantin Paul questioned the term tonic, given to all the cardiac drugs of which the different members had spoken. The model of tonics, he said, is sulphate of quinine. A tonic is a condensing drug which furnishes to the organism a force which it retains. If quinine is used in a very high fever, the temperature will come down to normal, but not below; now again, if in a very low temperature—much below normal, quinine be given, the temperature will go up to normal. Do the cardiac remedies act in this manner? No. If digitalis is given, it will restore the contractile energy of the heart; but if continued, its useful action will become dangerous.

He does not approve of sparteine nor caffeine. As to strophanthus or digitalis, he did not consider them as direct cardiac tonics, but as secondary ones, if the dose is not pushed too far. The increase of the cardiac energy appears only when the resistance of the blood-vessels diminishes by the fact of the diuresis. If diuresis does not take place, a few punctures with the thermo-cautery will evacuate the serosity; the vascular resistance diminishes, and soon after the cardiac contractions are reinforced; but if we give to an œdematous patient strophanthin, or digitalin when he does not urinate and in whom we have made no punctures, we are stuffing fuel in him which is sure to kill him. He thinks convallaria maïalis a good remedy to remove the œdema in arhythmic patients in whom the pulse remains weak. We must not forget alcohol, hot wine, ether, infusion of stimulating aromatic plants, and, finally, in aortic disease especially we have a powerful heart tonic—namely, a hypodermic of morphine.

Dr. Féréol sustained the views of M. Constantin Paul in regard to convallaria, and said that it can be taken for a long time without any danger to the patient.

Professor Semmola next read a short paper on "Sulphur as a Medical and Surgical Antiseptic." He had used sulphur for intestinal antisepsis, especially in typhoid fever; he also places pulverized sulphur in the bed of his fever patients.

M. Hallopeau read a communication on the "Nature of Alopecia and its Antiseptic Treatment." The author thinks that alopecia is always a parasitic disease, the parasite is situated very deeply on a level with the hair papilla. The disease is transmissible by contact. The treatment must be prophylactic and curative. The scalp must be very often washed with antiseptic solutions; the scalp must be modified by means of a blister and then Bardet's liquid is to be used; a well-treated alopecia ought to disappear in three or four months.

M. Hallopeau read another short paper in which he recommended certain antiseptics for the local treatment of syphilis. Iodoform can be used, or the different mercurial preparations, such as the acid nitrate of mercury, sublimated solutions; he recalled Diday's phrase, namely, that local treatment is always useful, oftentimes necessary, sometimes indispensable.

M. Jorissenne, of Liege, in a short communication, expressed his opinion that fissures of the anus are due to microörganisms; hence, he thought that the most rational treatment is the antiseptic method, which is at the same time analgesic. Corrosive sublimate solution has been found very effective; used as an ointment it is painless, easy of application, and efficacious; inunction must be made thoroughly, and the finger must be introduced at least for an inch and a quarter into the rectum.

PARIS, August 10, 1889.

A WINTER VACATION TO THE WINDWARD ISLANDS.

V.

TOBAGO was our next point, where we arrived long before daylight the next morning. But few of us went ashore, on account of the high surf, which prevented the ship taking cargo. It was a place of interest to us all, and Robinson Crusoe was the topic of the day. We spoke of him as an entity once among living men. We saw photographs of his cave; we speculated where was the beach upon which he saw footprints in the sand, and upon which rock the ship foundered. It was from Trinidad that the cannibals came, and they were beyond doubt man-eating Caribs. We consulted maps and studied ocean currents and prevailing winds, and the only island corresponding to his description that would intercept a vessel in a storm on the homeward voyage from the Brazils was Tobago. All this was soberly discussed and settled. Robinson Crusoe was real to all of us, as he will be to generations to come. He is not the only creation born of genius and of art that has cast a spell over the minds and hearts of men. These creatures are not shadows, but real, substantial, ruling the boundless dominion of the mind by the same agency that has placed the sceptre in the hands of those who rule—the subtile essence of the spirit. Have not as strong men sprung from the brains as from the loins of men? Are they not all the more potent from never having known the fetters and limitations of the flesh?

I risked the dangers of the surf and got safely ashore without wetting my camera. The little town of Scarborough straggled over a series of hills fairly buried in a wilderness of cocoanut palms, bread-fruit, nutmeg and broad-leafed plantains. One of the largest ceiba or silk-cotton trees which I met with among the Islands I saw here. It was an immense trunk with buttresses extending outward from two to five or six feet to the ground. The top extends widely and gives a dense and ample shade. It is a tree sacred to Obeah, and under it the negroes hold their fetich deviltry. The heat was so extreme that I was glad to secure a boat and return to the ship. On my way I secured a very good negative of the surf with the long line of palms that decorate the beach. It was an unfortunate trip for the ship, as she secured no freight, but the passengers were pleased with the opportunity to see the island.

Another day passed at sea and we were at the end of the route, and swung at the wharf at Georgetown, Demerara. We put up at the Tower Hotel, kept by a colored woman who told me that she was educating her daughters in Germany. The coolie, as in Trinidad, does

all the work and the negro of all shades may be as lazy as he pleases. He gets very little consideration here. Demerara is a Crown colony, and consequently is a white man's government. Georgetown is intersected by canals which keep up a system of irrigation as well as drainage. We saw several fine plantations, all with large coolie quarters attached. On our way we passed through the famous avenue of royal palms extending on both sides of a road near the coolie quarter of the town for about a mile. The sight was a beautiful one, but the photograph was disappointing, although a fair negative. Tropic foliage to be effective in a photograph must be massed. There is a beautiful botanic garden surrounding Government House where we found some very effective groups of foliage. The town has little of interest. The shops were not nearly so well stocked as at Trinidad. In fact Demerara is all sugar; that is its sole motive to exist, no other trade is cared for or invited. I, for one, was very glad after a dull and hot Sunday to get on board again and double back on our return voyage.

Barbadoes was our first return port. Here began the hopeless struggle of the good ship "Barracouta" for a cargo. She had failed at Georgetown and Port of Spain, but she was going to be in luck at Barbadoes; but the only cargo that she took on was much-needed water. At St. Lucia, St. Vincent, Antigua, Montserrat, it was only a few tierces here and a few bags there. At the latter place, 120 tierces of lime-juice were secured. This island is famous for its limes, which are exported by a rich company who have a monopoly of all the fruit. No lime-juice can be sold except through the company. It all goes to England, and thence over the world. It is worth mentioning that the tierces were shipped to England by the steamer company at the same rate the American freight was taken to New York —on the plan of what our railroad shippers call the "long haul," I suppose.

Had it not been for our stops on the return voyage, my expedition would have been a failure, photographically speaking.

I began my work subject to the unnecessary fear of over-exposure. The thin, flat negatives, characterized by a general want of contrast, which had been exhibited at the Camera Club by those who had been to the tropics, were explained as the result of over-exposure. At the same time, experts in outdoor work, whom we would find among the professionals, tell us to "stop down" and use our most rapid shutter. Nothing could be better designed to deceive the amateur accustomed to our northern summers with their clear, white lights, blue sky and dry air than the full glare of a tropic sun in a cloudless sky. The conditions favorable to rapid work seem the same, only greatly intensified in degree in favor of the tropics. But actually the conditions are reversed. A brief analysis of what exists at the tropics will, I believe, prove this. Of course, what I say relates to the marine tropics. In elevated and dry interiors within that latitude we have an approach to the conditions that prevail during midsummer in the temperate zone.

In the first place, the tropical objects that we have before the camera are full of contrasts. There is a peculiar glare on all objects exposed to full sunlight, with a corresponding depth to the shadows. There appears to be less diffusion in the light, like the shadows to electric light; but this is not so. It is simply contrast; the illuminated surfaces are very bright, the shadows very dark. In masses of tropic foliage this is largely due to their structure and density, but it is quite noticeable in architectural objects also. In wide scenic effects the same trait prevails.

In the mountains it is rare to find broad surfaces exposed. The sides are carved into ravines, pinnacle and cone merge into each other in aërial perspective. Dizzy and tortuous *arêtes* wind up the sides. The profiles of the mountains break abruptly, upheaving tier upon tier, like steps and winding stairways. Strange, weird, unearthly forms that tell of a world in ruins. All this is draped by a tropic profusion of foliage in variegated greens—a face of age in a mask of external youth. Everywhere you observe the marks of the fiery origin of these exquisite bits of earth, the fragments of what was once a mighty continent, caught like brands from the burning in the ages of its cataclysm. These surfaces are never illuminated alike; one side takes the full sun-glare, and the other, in deep shadow, appears black in contrast. Here the earth, with tropic mystery and grace, lends itself to artistic conditions met with rarely elsewhere. The heart of the enthusiastic amateur aches to get the marvellous scene upon his plate.

A difficulty that the photographer has to contend with, but which adds greatly to the infinite beauty of the mountains, and that would be clear to the artist with his pencil, is the dense volume of cloud that settles upon the summits. The trade-winds toy and sport with the clouds that by day and night rest in majestic masses upon the mountains. They are perpetually in motion; breaking into fragments and trailing purple streaks of shadows after them, winding in wreaths about the thin and twisted edges of *arêtes*, or piled in portentous columns of blinding whiteness when the sun impinged upon the mass, and with the blackness of a storm-cloud on the other side. The shadows of these dense cumuli often blot out all detail to the eye, even at noon-day. All long distance views were very thin, and required intensification to give even a poor print. Roughly stated, with the same stop and sensitiveness in the plate that would secure a good negative in the States, five times the exposure was required in the marine tropics with the most favorable conditions. I am speaking now of long-distance views. For near views and street scenes a good drop-shutter picture is nearly impossible.

All that I saw in the Islands had the same fault of under-exposure, although taken by men familiar with the conditions. Two causes contribute to this. The atmosphere is at a point of saturation with moisture. This actually screens the light, and just in proportion diminishes the actinic power. From this excess of moisture the second condition results, namely, the marked yellowness of the light, which diminishes greatly the actinic power. At Tobago, for instance, I made an exposure on the Government building. Its front was adorned with a portico. The columns were white. By reflection the yellowness of the light was overcome, and consequently gave good printing density, while the sky printed through, even under tissue-paper, a slaty-gray. Surf scenes, which were often very beautiful, suffered severely from under-exposure, as in order to get the effect you have no option but rapid work.

To Dr. Benjamin Sharp, of the Academy of Natural

Sciences at Philadelphia, I am indebted for instruction which put me right in the matter of exposure. I had the pleasure of meeting him at Tobago, so that I was enabled to correct the error on my return. I trust any of my photographic friends who go to the marine tropics will not commit my blunder, but will give ample time and full exposure.

When homeward bound we may say that our delightful expedition was ended. We had seen man under new conditions in the paradise of indolence—the Islands of the Afternoon, where no man toils.

ELY VAN DE WARKER.

THE INDIAN APPRECIATION OF TESTICULAR JUICE.

To the Editor of THE MEDICAL NEWS,

SIR: In a recent issue of THE NEWS, there appeared a note stating that the Indians of the Northwest have used a powder prepared from dried testes. To this material results are attributed which must be due merely to the imagination. No large knowledge is needed to show that such a powder must be devoid of all active property—for it is pretty nearly certain that the power possessed by testicular juice must be due to the presence in it of a *leucomaine*.

I have long known of a practice carried out by the Cheyenne Indians—the best favored, ablest, and the bravest of all the Indians of the Rocky Mountains and Plains. The older Indians encourage the eating of raw buffalo and antelope testes by the young warriors. They maintain that the juice confers on them increased power in all directions, especially as to the sexual function and bravery.

In 1859–60, when serving at the Post of Fort Merrion, New Mexico, I saw a young Cheyenne "buck" with two large testes, one in his mouth on which he was chewing vigorously, swallowing the juice as rapidly as he could, whilst out of the corners of his mouth the fat ran freely. The Indian did not look altogether happy as he went through his gastronomic feat, although he strove hard to preserve that stoical demeanor which every Indian is supposed to maintain under all circumstances. The older bucks stood around, giving an occasional grunt of satisfaction and approval, but the white spectators exhibited no little disgust and some were nauseated.

It now appears that the Indians were not wrong in their opinion of testicular juice. Again we learn—as saith the Preacher—that there is nothing new under the sun, and that which has happened once will happen again, and all is vanity.

NEWS ITEMS.

The Prophylaxis of Tuberculosis.—In our issue of August 24th we gave the report of the French Commission on Tuberculosis. The discussion of the report was continued at the meeting of the Académie de Médecine held August 13th. After a lengthy debate, Dr. Villemin closed the discussion by saying that the danger from the sputa of phthisis was unquestioned, and that the Commission's recommendations for strict hygienic measures and disinfection were endorsed. In the pursuance of these measures, the careful disinfection of railroad coaches should not be omitted. Only, the question of the danger in using the flesh of tuberculous animals was still unsettled; he, therefore, proposed that a committee be appointed to investigate this most important subject.

The Academy unanimously acquiesced in this proposal, and a committee was appointed consisting of Drs. Villemin, Verneuil, Germain Sée, Cornil, and Dujardin-Beaumetz.

A New Swiss Pharmacopœia.—A new Swiss Pharmacopœia is shortly to be published. A request has been sent, by the collaborators, to Swiss medical societies and practitioners, requesting suggestions as to the introduction of new remedies and the retention of old ones.

Death from Suspension.—Another case of death has occurred from the suspension treatment of locomotor ataxy—this time in Italy. The case, which is reported in the *Riforma Medica* of July 19th, occurred in the clinic of Professor E. Galvagni.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM AUGUST 20 TO SEPTEMBER 2, 1889.

BAILY, JOSEPH C., *Lieutenant-Colonel and Surgeon* (Medical Director Headquarters Department of Texas).—Is granted leave of absence for one month.—*S. O. 54, Headquarters Department of Texas, San Antonio, Texas*, August 17, 1889.

Commanding Officer at Jackson Barracks, Louisiana, telegraphs the Adjutant-General of the Army that HARVEY E. BROWN, *Major and Surgeon*, died at Jackson Barracks to-day, at 1.40 o'clock P. M.—*Jackson Barracks, New Orleans, La.*, August 20, 1889

POPE, BENJAMIN F., *Major and Surgeon.*—Is granted leave of absence for one month, with permission to apply through Division Headquarters for an extension of two months.—Par. 7, *S. O. 54, Department of Texas*, August 17, 1889.

By direction of the Acting Secretary of War, WILLIAM S. TREMAINE, *Major and Surgeon*, now on sick leave of absence at Buffalo, New York, will report in person to the commanding general Department of the Missouri, for assignment to temporary duty at the post of Fort Leavenworth, Kansas.—Par. 4, *S. O. 198, Headquarters of the Army, A. G. O., Washington*, August 27, 1889.

PORTER, JOSEPH Y., *Captain and Assistant Surgeon.*—The resignation has been accepted by the President, to take effect August 29, 1889.—Par. 11, *S. O. 200, Headquarters of the Army, A. G. O.*, August 29, 1889.

BANISTER, W. B., *First Lieutenant and Assistant Surgeon.*—Is granted leave of absence for fifteen days.—Par. 2, *S. O. 82, Headquarters Department of Arizona, Los Angeles, Cal.*, August 23, 1889.

PROMOTIONS.

MATTHEWS, WASHINGTON, *Captain and Assistant Surgeon.*—To be Surgeon, with rank of Major, July 10, 1889, vice Town, promoted.

EWING, CHARLES B., *Assistant Surgeon.*—To be Assistant Surgeon, with the rank of Captain, July 5, 1889, after five years' service, in accordance with the Act of June 23, 1874.

MCCAW, WALTER D., *Assistant Surgeon.*—To be Assistant Surgeon, with rank of Captain, August 20, 1889, after five years' service, in accordance with the Act of June 23, 1874.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FROM AUGUST 3 TO AUGUST 24, 1889.

LONG, W. H., *Surgeon.*—To proceed to Gallipolis, Ohio, as inspector, August 7, 1889.

WHITE, J. H., *Passed Assistant Surgeon.*—Granted leave of absence for thirty days, on account of wound, August 16, 1889.

CONDICT, A. W., *Assistant Surgeon.*—Detached from Revenue Bark "Chase," and ordered to Louisville, Kentucky, for temporary duty, August 19, 1889.

GROENEVELT, J. F., *Assistant Surgeon.*—Ordered to South Atlantic Quarantine Station, for temporary duty, August 8, 1889.

ORIGINAL LECTURES.

LENTICULAR REGULAR ASTIGMATISM.

A Lecture delivered before the Post-Graduate School of Ophthalmology. Session of 1888–89.

BY SWAN M. BURNETT, M.D.,

PROFESSOR OF OPHTHALMOLOGY AND OTOLOGY IN THE UNIVERSITY OF GEORGETOWN; OPHTHALMIC SURGEON TO THE GARFIELD HOSPITAL; AND DIRECTOR OF THE EYE AND EAR CLINIC AT THE CENTRAL DISPENSARY, WASHINGTON.

GENTLEMEN: We have learned from our preceding studies that the refracting apparatus of the eye consists of the cornea and crystalline lens. We have also learned that the ordinary so-called anomalies of refraction are not, strictly speaking, anomalies of refraction at all, but only variations in the anterior-posterior diameter of the eyeball, the refracting apparatus proper taking but little part in the production of either myopia or hypermetropia. I have myself demonstrated by a large number of measurements of the cornea by means of the ophthalmometer of Javal and Schiötz that the refraction of the cornea, which is the principal refracting medium of the eye, is no sort of an index to the general refractive condition of the eye as regards its being myopic or hypermetropic.[1] The refraction of the cornea of an emmetropic eye I have found may vary from 47 D. to 39 D.; the average being from 43 D. to 45 D. And I have found, also, that in myopia there may be a low corneal refraction and in hypermetropia a refraction of the cornea in excess of some highly myopic eyes.

We are, unfortunately, not in a position to determine with the same ease or accuracy the refraction of the crystalline lens. We cannot measure the curvature of its surfaces as readily as we can those of the cornea, but we have no reason to suppose from what knowledge we have that its static refraction varies sufficiently in different individuals to bring about any important changes in the general refraction of the eye. Moreover, the changes at the fundus of the eye in myopia which we are able to distinguish by means of the ophthalmoscope, in the form of stretching and thinning of the choroid, and the evident flattening of the globe, which is often apparent on external inspection in hypermetropia, are quite sufficient proofs that the true cause of general ametropia is an alteration in the position of the retina in its relation to the focal point of the refracting apparatus of the eye as a whole. Whenever, therefore, we use the term "anomalies of refraction," we should add, mentally at least, "in relation to the length of the eyeball."

The case is quite different, however, when we come to astigmatism, and particularly to the regular form in which the refraction in the meridians at right angles to each other is different. It is true that an attempt was once made to attribute some astigmatic effect to an irregularity of the curvature of the fundus at the macula lutea, but it certainly cannot occur very often nor to any considerable extent in the production of regular astigmatism.

We are now able to assert that in the vast majority of cases regular astigmatism has its seat wholly in the cornea, and is thus really the only anomaly of refraction, properly speaking, among the various forms of ametropia. In the statistics already alluded to, it was found that only in a rather small minority of cases was the total amount of astigmatism essentially different from that found in the cornea by the ophthalmometer of Javal. My further experience extending now to several hundred cases in addition to those reported in the paper referred to, has only more strongly confirmed the opinion then expressed, and it is, moreover, in perfect accord with the observations of all others who have made any extended use of this valuable instrument. And I wish to state again, with added emphasis, my firm belief in the great practical utility of this most ingenious apparatus. In my treatise on astigmatism, published in 1887,[1] in which is to be found the first description of the instrument printed in English, I stated that in my opinion it was the most important instrument for positive diagnosis placed in our hands since the invention of the ophthalmoscope. The constant daily use of the instrument since that time has in no way modified the favorable opinion then expressed, and I never deem a case of refraction complete in its examination until the cornea has been measured in all its meridians. I am pleased to know that in this position I am sustained by so high an authority as Prof. Snellen, of Utrecht, the successor of the immortal Donders. It has been objected in some quarters, that while ingenious it is not practical. On the contrary, I claim that it is more easily and successfully manipulated than any other of the apparatus of the ophthalmological armamentarium.

Its more extended employment is prevented, I think, by two causes. First, its cost, which in this country has been about one hundred and fifty dollars, inclusive of duty; though that, perhaps, has not been so much of an obstacle as the second, which is the great difficulty of getting them when wanted. It has sometimes taken three years to get one after it has been ordered. This latter difficulty however, seems now likely to be obviated by the undertaking of a new firm in Paris (A. Goubeaux, 216 Boulevard St. Germain) which promises to keep a stock of the newest and best patterns on hand at two hundred and fifty francs net.

The instrument is used but little in Germany, which can be attributed only to an unworthy national pride, which prevents the Teuton of this generation from accept-

[1] An analysis of the refraction of 576 healthy human corneæ examined with the ophthalmometer of Javal and Shiötz. Trans. Amer. Oph. Soc., 1888.

[1] A Theoretical and Practical Treatise on Astigmatism. J. H. Chambers, St. Louis. Pp. 123–133.

ing anything as good "which comes out of Nazareth." As Javal himself once wrote me "when there appears a German modification of the ophthalmometer then it will come to a general acceptance." As, however, Javal has produced an instrument so nearly perfect for its purposes that it is scarcely possible to make any modification that shall be an improvement, we fear that the most practical astigmometer yet devised must remain to the credit of the French. It is curious, too, that it is used but little, if at all, in Great Britain. When, however, the British are once brought to a realizing sense of its true merits, and know its practical advantages, their customary conservatism will give way and they will begin to employ it.

The constant use of the ophthalmometer (or more properly the *keratometer*, since with it we measure the refraction of the cornea alone) has enabled us to discover the important fact to which allusion has been made, that regular astigmatism is for the most part resident in the cornea and that there are very few corneæ that are perfectly spherical in form; a small amount of corneal astigmatism—rarely less than 0.25 D.—being found in eyes which to the test are emmetropic.

Another interesting fact which has been brought to light by those examinations, is that corneal astigmatism is, with the rarest exception, "according to the rule"—that is, the meridian of greatest refraction is the vertical The opposite condition, where the greatest refraction is in the horizontal meridian and "contrary to the rule," must then be sought for in some other part of the refracting apparatus. These facts lend support to the opinion that the pressure of the lids plays an important part in the production of the common forms of astigmatism.

But while it is a fact that the corneal astigmatism commonly represents very nearly the total astigmatism of the eye, the exceptions are frequent enough to merit our attention and interest.

Of course, the only other part of the eye which could possibly be concerned in the production of astigmatism is the crystalline lens. It is a curious fact in the history of astigmatism that the first recorded case of the anomaly was demonstrated to be resident in the lens. Thomas Young, the great English philosopher, who gave us numerous and valuable facts, hints, and suggestions in regard to the pure optics of the eye, but led succeeding generations entirely astray on the subject of color-perception, on immersing his eye in water, thereby eliminating the refraction of his cornea, found his astigmatism still persistent. He conceived, and I think very properly, that the astigmatism was due to a position of the lens oblique to the visual axis. It is further interesting to note that the usual law of lenticular astigmatism being "against the rule" was kept in this case, since the far point of his eye for rays diverging horizontally was seven inches, and for those diverging vertically was ten inches, making an astigmatism according to his own calculations of one-twenty-third.

We demonstrated to you in the earlier part of this course how a spherical lens held obliquely to incident pencils takes on an astigmatic action, having two focal lines at right angles to each other and at different distance from the lens, instead of a single focal point. This view of the lenticular cause of astigmatism was the one universally accepted until the measurements of the cornea made in Helmholtz's laboratory in Heidelberg by Knopp, in 1859, led to the discovery that the cornea was the chief seat of the anomaly, and that Young's case was exceptional. Some years later, however, Dobowolsky found, in making some measurements of the cornea by means of the ophthalmometer, that the corneal astigmatism did not always express the exact amount of the manifest general astigmatism, being usually greater. He assumed, therefore, an astigmatism of the lens, opposite in kind to that of the cornea, with a neutralizing influence, and which he thought was brought about by an unequal contraction of the ciliary muscle such that the curvature of the lens instead of being, as in its normal condition, that of a sphere, would assume that of a spheroid with one meredian of greatest and one of least refraction at right angles to each other. He considered, as have others since he wrote, that this unequal contraction of the ciliary muscle was voluntary, or, at least, brought about by the instinctive desire of the individual for the most distinct vision he could get. Javal, among others, has also found that a certain amount of corneal astigmatism is in early life not incompatible with normal vision, becoming "manifest," however, as soon as the accommodation begins to lose power with age.

It has always been a difficult matter for me to understand how such an unequal contraction of the ciliary muscle in its various meridians was possible; nor do I fully appreciate teleological mechanism which enables the muscle to contract with just the inequality that shall neutralize an existing anomaly in the cornea. However, if the fact is as many competent observers state, we must accept it whether we can account for it to our perfect satisfaction or not. Certainly, we know that corneal astigmatism is often covered up by lenticular astigmatism of an opposite character, and becomes manifest only after paralysis of the ciliary muscle.

It is our habit, therefore, when we find the corneal astigmatism, as measured by the keratometer, to be in excess of that revealed by a careful examination by the test-glass, the ophthalmoscope, and skiascopy, to paralyze the accommodation for further examination. I say "careful" advisedly, for very often a small amount of mixed astigmatism escapes detection unless it is diligently sought for. Very often a cylinder of 0.5 or 0.75 D. of an opposite kind and with its axis at right angles to that which has given the best, but not perfect vision, will advance the visual acuteness from $\frac{5}{6}$ to $\frac{5}{5}$, satisfy all the demands of the corneal astigmatism, and render the use of a mydriatic unnecessary. It is only when no glass or combination of glasses comes up to the requirements of the astigmatism of the cornea, that I consider an elimination of the accommodation absolutely demanded for the diagnosis of astigmatism. As far as concerns general ametropia and the presence of a "latent" hypermetropia, it is another matter and the custom of different and equally competent authorities is by no means the same. As for myself, I do not consider a pathological spasm of the accommodation to be the almost constant accompaniment of ametropia, as seems to be the prevalent opinion in some quarters.

The manner in which the accommodation influences the character of astigmatism of the eye, as a whole, is not confined to the partial contraction of the ciliary muscle already alluded to. The contraction of the ciliary muscle in its entirety has a very pronounced

and variegated effect upon the general astigmatism. As you can readily understand, the act of accommodation in moving forward the focal lines of the interval of Sturm can convert a simple or compound hypermetropic into a simple myopic or even a compound myopic astigmatism; or might mask a mixed astigmatism, converting it into the simple or compound myopic form.

I think experience has shown that there is a desire, for most visual purposes, to have the vertical lines most distinct when all cannot be made so. This accounts, in my opinion, for the conversion, in so many instances, of hypermetropic astigmatism, axis 90°, into the myopic form, axis 180°, by a tonicity of the ciliary muscle which, from long habit, becomes a fixed and, as it were, a normal condition, and which can often not be made to disappear even after a prolonged use of atropine.

But I believe that the accommodation, acting as a whole, may influence astigmatism in yet another way, and in a manner to which but little, if any, attention has been paid By a rapid alternate contraction and relaxation of the ciliary muscle, first one and then the other focal plane is brought on the retina, and thus, while all the lines of a test-letter, for example, are not seen distinctly at once, they are each seen clearly in such rapid succession as to enable the individual readily to distinguish the whole. This, however, can only happen when the ciliary muscle is very strong and the lens very plastic, as it is in early life. As soon as the lens begins to harden it loses its facility in thus rapidly responding to the accommodative impulse, and the corneal astigmatism, which was "latent," becomes manifest. And, in my judgment, many, if not a majority, of those cases of what were supposed to be partial contraction of the ciliary muscles in early life fall into this category.

There is still another form of lenticular astigmatism, the corollary of this, of which I have not seen mention made anywhere. My attention was called to it by my friend, Prof. Harkness, of the Naval Observatory, who takes a great interest in physiological optics as well as optics generally. He finds, he tells me, that since he has arrived at the age of fifty years, after using his accommodation in reading for some time, there is developed quite a perceptible amount of astigmatism for distance, revealing itself particularly in the appearance of distant points of light. He explains this, and, I think, correctly, by assuming that the lens, after the stress of accommodation has passed off, does not assume its normal spherical shape at once or equally, some sectors being less pliable than others and requiring a longer time to get into the normal form.

But lenticular astigmatism due to an oblique position of the lens, such as described by Young, is undoubtedly of more frequent occurrence than is generally supposed. The obliquity may be due to traumatism, as in the following case, which was recently under observation:

A boy of fifteen was struck in the left eye with a bean discharged from a bean-shooter. When first seen, some ten days after the accident, there were found two ruptures in the choroid downward and inward from the optic disk, and a dislocation of the lens upward and inward. The lower and outer edge of the lens was clearly visible through the pupil, which was very much dilated, as the result of the blow, and it showed striations of opacity extending from one to two millimetres toward the centre. The iris was tremulous at its upper inner portion. Skiascopy gave myopia of 5 D., axis 45° (meridian at 135°, corresponding approximately to the direction of the dislocation), and M. 1. D in the opposing meridian. In that eye V. $> \frac{5}{LX}$; with $= 0.75 \bigcirc - 3.5$ D. 45°, it came up to $\frac{5}{XVIII}$. The keratometer showed both corneæ to be spherical, each having a refraction of 44 D. in all meridians. The right eye was emmetropic. At the end of four months the conditions were essentially the same. In this instance there can be no doubt that the astigmatism was lenticular, and due to an oblique position of the lens, since a prolonged use of atropine failed to change the condition in any important degree.

But aside from these traumatic cases, there remains a category where the obliquity of the lens is evidently congenital. Moderate degrees of obliquity, such as to cause 0.5 D. of astigmatism, I believe to be rather common. We often find the corneal and total astigmatism to differ by that amount, even when we are sure that the accommodation does not come in as a factor. We generally find, also, that in such cases the general astigmatism is less than the corneal. We can readily understand this when we remember that, while corneal astigmatism is "according to the rule," the lenticular astigmatism is due to a rotation of the lens on its vertical axis producing an astigmatism "contrary to the rule," and, of course, neutralizing in its effects. A case which very fully illustrates this condition came under my observation only a few days ago.

A young man of twenty-four, had vision in L. $= \frac{5}{XVIII}$, in R. $= \frac{5}{V}$. Both corneæ were astigmatic, L. 1.25 D. 30°, R. 1.25 D. 20°—that is to say, the axes were both inclined to the right, and not both in or out, as we usually have it when the axes are oblique. No glasses improved vision in the right eye, but a cylinder of — 2. D. axis 125°, very much improved the vision in the left. Skiascopy and the ophthalmoscope gave essentially the same results. This was one of the cases where I considered a paralysis of accommodation necessary for a full and complete examination. As he was in government employ, and could not spend ten days in idleness under atropine, I ordered him hydrobromate of homatropine gr. j, water ʒj, a drop to be put in either eye every fifteen minutes for two hours. At the end of that time all voluntary accommodation was gone. With + 6 he could read No. 1 of Snellen at six inches, but not at seven or five inches. His distant vision in R. with + 0.5 was still $\frac{5}{V}$. In L. V. $= \frac{5}{XXIV}$, and with $+ 0.5 \bigcirc - 2.25$, 125° $= \frac{5}{IX} +$; skiascopy and ophthalmoscope corroborating. Here we have the same corneal astigmatism in both eyes, but while there is emmetropia in the one, in the other there is an astigmatism almost double that of the cornea in the other. I think that in this case we are justified in considering the accommodation entirely abolished, and the whole phenomena can be beautifully and consistently accounted for on the supposition of a rotation of the lenses symmetrically on their axes—at about 45° inward in both eyes (that is, 45° R., 135° L.). Such a position of the lenses would neutralize the corneal astigmatism of the right eye at 30°, and increase it in the

left at 125°. It is interesting to note, in this connection, that those congenital dislocations of the lens which are visible, are usually upward and inward.

In another case of a boy of fourteen, examined the same day, there was a corneal astigmatism, "according to the rule," of 1 D. in L. and 1.25 D. in R., but no corresponding demonstrable general astigmatism. V. $= \frac{5}{v}$; no glasses improving. Under atropine, thoroughly used, the only thing developed was a H. of 1 D., but no astigmatism whatever.

Such cases as these are by no means rare, while those of less degree are quite common in my experience, and but for the fact that our allotted time is already spent, many other illustrative examples could be offered. But I think I have already given sufficient to show you that there is a regular astigmatism of the lens which is of sufficient importance to be searched for, and that the lenticular astigmatism due to an oblique position of the lens is probably a more frequent factor in neutralizing corneal astigmatism than a partial contraction of the ciliary muscle.

ORIGINAL ARTICLES.

THE MINERAL SPRINGS OF COLORADO.[1]

BY CHARLES DENISON, M.D.,
OF DENVER, COLORADO.

AMONG the various natural advantages to be found within the borders of the Centennial State, few if any are more abundant and wonderful than the mineral, cold, and thermal springs. This richness is not astonishing to one who is conversant with the remarkable geology of this section. The ore "belts" and ore "shutes," showing different combinations of the precious or base metals; here the salines, there the sulphurets; or again the chlorides, carbonates, or chalybeates, predominating (and sometimes all of them existing together) are but indices of the processes which in the Rocky Mountains have produced a great variety of medicinal waters, through igneous, electrical, or other natural means.

The "carbonates" of Leadville, the sulphurets of the San Juan region or of Clear Creek County, or the chlorides of Custer County, show a marked similarity in their combinations to the neighboring mineral springs. It is claimed that the famous Bassick and Bull Domingo mines in the Wet Mountain valley are but the remains of tremendous thermal springs, where boulders were coated with metals and salts, and the surrounding rocks also became impregnated for considerable distances. And there are many miners who believe the great mother spring or volcano will yet be found which once threw up that large chloride deposit extending over miles in area near Silver Cliff.

[1] Read before the American Climatological Association, June 25, 1889.

The task of describing all the mineral waters of Colorado is impossible at this early stage of Colorado's development, as the data is yet too crude and incomplete. However, the chronicler of a few years hence will have a great advantage, when the complete analyses of Colorado mineral waters, authorized by the last State legislature, shall have been completed.

The writer takes pleasure in referring to Dr. Solly's published description of the "Manitou" mineral waters, and at the same time feels compelled to pass by the wonderful Pagosa, Ouray, Uncompaghre, Tomichi, Wagon Wheel Gap, Canon City, Poncha, Cottonwood, and the hot springs of Middle Park. He will confine himself to a description of four of the groups, chiefly in northern Colorado, which he has personally investigated, namely, Steamboat Springs, the Siloam and Glenwood Springs group, the Seltzer at Springdale, and the thermal waters at Idaho Springs; adding a description of the latter point as a representative mountain health station.

STEAMBOAT SPRINGS, *Routte County*.

One of the most wonderful collections of mineral springs in America is to be found in northwestern Colorado, west of the main range of the Rocky Mountains; along both banks of the Bear, or Indian Yampa River, and above the point where the Elk River joins it from the north.

The town is in its infancy, and the springs are named Steamboat, because of the likeness of one of them to the puffing of a steamboat, with its peculiar rumbling, swishing, and hissing noise. This spring, although cold, is so freighted with gases, that a regular spouting to the height of about three feet is caused through a hole ten inches in diameter in the solid rock.

The analysis of this spring is as follows:[1]

Carbonate of soda	75.24
Oxide of iron	a trace
Sulphate of potassa	8.39
Sulphate of lime	21.64
Sulphate of magnesia	11.76
Chloride of sodium	200.76
Evaporation by calcination.	2.74
Total	320.53
Gases { Sulphuretted hydrogen, Carbonic acid.	

The remarkable fertility of this neighborhood in variety of mineral waters, is instanced by the fact that within forty feet of this gas spring there are three flows of water which give different colored deposits on the grass and stones over which they flow.

There are forty or fifty springs in all, on either

[1] All the analyses are reduced to a like standard, namely, parts of mineral or solid substances in 100,000 of spring water.

side of a limestone and quartzite ridge, running northwest and southeast, the valley of the Bear at this point running east and west.

The springs are at present reached by stage, about 100 miles south from Rawlins, Wyoming, on the U. P. R. R.; 75 miles north from Russell, on the D. & R. G. R. R., and 85 miles northwest from Hot Sulphur Springs, in Middle Park, Colorado, which is 48 miles from Georgetown, on the Colorado Central R. R. The latter route, about 180 miles from Denver, has been the one usually chosen by tourists, but the Russell route just opened is shorter.

It is only a question of time, when some enterprising railroad corporation will extend the iron rails into this valley of the Bear River.[1]

The altitude of the springs is about 6500 feet above sea level, and it is somewhat colder than the same elevation on the eastern slope of the Rocky Mountains. The air is decidedly bracing and very dry, and invalids generally have been known to become robust and healthy by a more or less prolonged stay in this section. It should of course be noted here, that only those most fit for such a life of "roughing it" have thus far gone into the Bear River valley. The springs have been taken up by individuals and are included in the domain of the Steamboat Town Company.

Among the mineral springs, there is one of which it is especially delightful to drink. This is the *Iron Spring*. The water is cold and contains carbonic acid in excess, as well as the iron; so that, while drinking, it tastes much as does freshly-drawn Vichy, and one can imbibe more of it at one time than can be done with any other water of which the writer is acquainted. In 100,000 parts of the Iron Spring water are contained

Oxide of manganese	a trace
Carbonate of iron	38.40
Sulphate of potassa	11.15
Sulphate of soda	39.02
Sulphate of lime	71.86
Sulphate of magnesia	40.79
Chloride of sodium	104.20
Alumina	a trace
Evaporation by calcination	50.58
Organic matter	3.41
Total	359.41
Gases	Sulphuretted hydrogen, Carbonic acid.

Besides being one the best chalybeate waters known, this has been found especially efficacious in dyspepsia.

About half a mile from the main group of springs is the *Bath Spring*. This is a hot spring—temperature 103° F.—which bubbles up in a pool twelve feet in diameter. A bath in this spring is peculiarly delightful, probably in part because of some chemical combination on the surface of the bather's body, which is covered, while in the water, with minute white bubbles.

The analysis of this water is as follows:

Carbonate of lime	23.50
Sulphate of potassium	a trace
Sulphate of soda	9.55
Sulphate of magnesia	10.43
Alumina	a trace
Evaporation by calcination	4.36
Total	47.84
Gases	Phosphoric acid, Silicic acid.

There are two other hot springs in this vicinity, one of which, with a large flow of water, is situated about five miles north of Steamboat Springs proper, and has a temperature of 156° F. This water, and that of several other important members of the group, have not yet been analyzed.

There are two or three cold boiling springs, with large flows of water, decidedly sulphurous in nature.

Then there are various combinations of iron with sulphur. One spring boiling up in a pool thirty feet in diameter, is called the "Milk Spring" because the water is white as milk. This water has a sweetish, salty taste, and cattle seem to like to drink of it. There are two or three other springs which are probably also composed of magnesia either alone, or in combination with iron, is a principal constituent. One of the springs is decidedly saline, the water proving actively purgative if taken in sufficient quantities.

There are pools of mineral water not yet investigated and a cave formed by the deposit from mineral water. This excavation is so filled with gases, that one's lungs immediately become exhausted if he tries to remain there.

Besides all this there is plenty of good drinking water not mineralized; all of which goes to show that Steamboat Springs, because of its natural advantages, is destined to become a very attractive

[1] There are inducements sufficient in the coal, iron and grazing advantages, not to mention one of the most attractive—to the genuine sportsman—summer resorts in the United States; for here, according to the writer's experience, one can catch more trout in an hour, and find larger game in hunting, than in any other portion of Colorado. For instance, during a half day's hunt in "85" after a bear and elk, the latter of which he shot, he saw seventeen deer and three elk, in bunches numbering from one to three, just west of the Elk River. Of course, the numbers are gradually decreasing, but the region is peculiarly adapted to the grazing and haunts of game, as well as for hunting on horseback. The mountains are not abrupt as in the main range, but rise by easy graduations from the beds of the streams to a distance of from three to eight miles away. These hills and valleys in summer are covered with rich grass, which the fortunate possessors of the bottom lands use as pastures, while they cut hay from their ranches to tide over the two or three months of winter, with the deep snow which is characteristic of the upper half of the Bear River valley.

resort, for the tourist and invalid, especially in the summer time.

The analysis of the waters were made by Prof. E. J. Mallett, Jr., formerly of the School of Mines, at Golden, Colorado.

SILOAM SPRINGS, *Garfield County.*

These springs consist of five outflows along the banks of the Grand River, below where the Eagle River empties into that noble stream, and just west of the boundary line of Eagle County. The elevation is about 6000 feet above sea level and they are warm, or hot, being from 94 to 104 or more degrees Fahr., and contain a combination of salines very similar to the waters found at Saratoga.

According to Sir Henry Thompson, the heat intensifies the effect of the medicinal ingredients which such waters contain. This is undoubtedly the fact, for a single glass of this water taken hot is a purgative under ordinary circumstances. This does not appear to be otherwise explained according to the partial analysis of the Bath or Warm Sodium Spring, by Prof. Regis Chauvanet, of the Colorado State School of Mines, unless the effect mentloned be due to the sulphate of lime.

	Parts in 100,000.
Bicarbonate of lime	21.96
Bicarbonate of iron	1.99
Sulphate of lime	65.70
Chloride of sodium	948.42
Chloride of magnesium	21.78
Silica	.40
Total	1060.25

Or 616½ grains in a gallon.

A much larger flow of water has been developed since the above analysis was made—*i. e.*, in the Cave Spring, nearer the head of the Canon of the Grand, about half a mile further down the river than the warm Sodium Spring.

The tunnel or entrance to the cave is about five feet wide, and the flow of water which reaches across the bottom is six inches or more deep, the temperature being about 103° F. This cave is constantly full of warm steam, and the hot water pours from the porous rock by many openings, as in the caves at Glenwood Springs, sixteen miles further down the Grand River.[1]

There is, in other respects, much similarity between these outflows and those at Glenwood.

On the opposite side of the river from the Cave Spring, between an island and the main land, is "The Pool," which gives the town its name of Siloam, after the spring and pool made memorable in Bishop Heber's lines, "By cool Siloam's shady rill," etc. This pool is over one hundred feet in diameter, with mud banks formed largely of the chemical deposits from the large flow of hot mineral water which comes up in its centre. Neither the waters of the Pool, the Cave Springs, or of the Boiling Spring, farther down the river, have yet been analyzed, but they are heavily mineralized, and the latter especially is said to be agreeable though peculiar in taste, and to have a decided effect upon the action of the kidneys, as well as upon the bowels. Though the total flow from Siloam's five principal springs is less than that at Glenwood, yet it is approximated by a good judge to be over ten thousand gallons an hour.

The analysis already given shows a remarkable similarity to the Saratoga group, especially the Eureka, while the total constituents are like the Empire and Congress flows. As alterative, laxative, and diuretic waters, these alkaline saline springs are destined to take a prominent place among the medicinal springs of America. It is the intention of the promoters of the town to improve the springs by adding bathing establishments, and hopes are entertained of having a Sanitarium of considerable proportions built at this point. The Denver and Rio Grande Railroad is completed through the town, and some considerable work has already been done on the opposite side of the river, on the joint roadbed of the Burlington and Union Pacific railroads.

The beautiful valley, in the centre of which are the hot springs, and around which rise magnificent mountains, one above another, till a height of 10,000 to 14,000 feet above sea level is reached, affords many advantages for a health resort.

Among the natural attractions near by are the wonderful Canon of the Grand River, equal in grandeur and sublimity of views to any of Colorado's gorges, and the "Deep Creek" Canon, three miles northeast, crossed by the road leading to "Sweet Water Lake," twelve miles distant. This lake is a most charming body of clear water in which, as well as in all the streams mentioned in this article, are quantities of trout, which can be taken in large numbers by a good fisherman at the right season of the year.[1] Near this lake are some interesting caves.

About nine miles from Siloam to the north, and at an elevation of 9000 feet above sea level, is an area uncovered by snow in the coldest winter, where a cloud of steam exudes from the earth. This is supposed by some to be an escape of gas and steam from the source of the hot springs at Glenwood and Siloam.

In other ways this region about Siloam is wonderful and interesting, not to omit the utility of unlim-

[1] At the entrance to this cave a substantial bath house and across the river the first hotel of Siloam have just been completed.

[1] Around these places—*i. e.*, up in the mountains near "timber line"—a persevering hunter will undoubtedly be rewarded by coming across a deer or antelope, and occasionally a bear, though the chances are more than even that he will say he "has not lost any bear" should he meet a member of the bruin family.

ited amounts of gypsum, limestone, granite, marble, lumber, coal, and carbonate veins containing silver.

THE SELTZER SPRINGS.

These springs are situated at Springdale, Bou'der County, a small mining hamlet, ten miles from Boulder, the county seat, which is the nearest railroad point. There is a post-office and daily mail. Stage leaving Boulder at 1 P.M. daily, also reached by daily stage from Lyons, about the same distance away, on the line of the Denver, Utah & Pacific Railroad. The location is on James Creek, a clear mountain stream, surrounded by wooded mountains, and in the midst of picturesque scenery. Trails and foot-paths lead to the summit of lofty peaks in the vicinity, from which can be had grand views of the snowy range eight to ten miles distant. These points also command sweeping views of the plains to the north, south, and east, spread out like a vast ocean.

The subjoined analysis of the Seltzer Springs by Dr. Jackson, State Assayer of Massachusetts, indicates their value:

Bicarbonate of soda	9.37
Carbonate of lime	74.29
Bicarbonate of magnesia	1.14
Bicarbonate of iron	6.86
Sulphate of soda	184.46
Chloride of sodium	8.51
Silicate of soda	6.86
Iodide and bromide of sodium	2.23
Total	293.72

The formation of the springs is in solid granite. The water flows freely out of the crevices of the rock and is strongly impregnated with carbonic acid gas.

The springs are situated near the edge of the creek. The drinking-water, separate from the mineral spring, is pure and soft and is obtained from wells. The baths are used extensively, with excellent results, in chronic rheumatism, the water being heated artificially.

The climate differs only from the "valley," or plains, in the cooler nights in summer. The mean temperature is slightly below that of Denver—about 47° for the annual average. The attractions of the neighborhood are the mining camps and mines in the immediate vicinity, the walks and rides in all directions presenting varied and picturesque views, and the trout-fishing in the St. Vrain, a few miles distant.

The springs were discovered in the early history of the Territory, and the waters have been used by those living in the vicinity ever since.

There is a small but well-appointed hotel, and several cottages connected, where every convenience and comfort can be had at moderate prices.

The flow of water from the principal spring is about the capacity of a 1-inch pipe, with, say, 1 foot of pressure. The soil is light and gravelly, and there are no stagnant pools, as the swift-running creek supplies a channel for quickly draining off all refuse.

When the analysis is compared with those of the celebrated springs elsewhere (reduced to a uniform standard—*i. e.*, parts in 100,000 of water), its place is well established among such springs as Bethesda, Waukesha; Hot Springs, Arkansas; and Old Source, St. Moritz, Switzerland; Gastein, Austria; Seltzer, Saratoga. The Bethesda, with one-seventh as much salt—solid ingredients—as the Springdale water, must get its superior value, if it has any, from substances the analysis does not mention. We would be inclined to offer the same excuse for the waters of the Hot Springs, Arkansas, and the Gastein, in Austria, except for their silica, if it were not for their great heat, which being natural, is believed to be much more advantageous. The Springdale Seltzer analysis, as a measure of valuable chemicals, seems to be superior, especially in quantity, to all those named, which it decidedly resembles. But the closest analogy is to the waters of the Seltzer Springs, Saratoga, and the Old Source spring, at St. Moritz, Switzerland. The Springdale Seltzer, though weaker than the Saratoga Seltzer in salines, is stronger in iron, which is in the excellent form of the bicarbonate. It resembles the St. Moritz, Switzerland, except it has six times as much sulphate of soda. The additional alterative influence of the silicate of soda and of the iodide and bromide of sodium, which the Springdale water contains, would place it above both the other two mentioned. It is a decided tonic and alterative water. It is alkaline and slightly diuretic, effervescent and agreeable, and is indicated in dyspepsia chiefly, in convalescence from fevers and debilitating diseases, in chlorotic disorders and in anæmic states where iron is needed. The beneficial effects in case of diabetes and in other chronic diseases of the kidneys have been noted by the writer.

IDAHO SPRINGS.

Idaho Springs is one of Colorado's promising mountain towns. It owes its prosperity to the hot medicinal springs which are found there, and after which the town is named; to the climate and natural attractions of the locality, and to the gold and silver mines in the mountains near by. It is thirty-five miles distant from Denver and reached in two hours on the Colorado Central, a narrow-gauge branch of the Union Pacific Railroad, and its elevation above sea level is 7512 feet at the railway station. From the plains, two thousand feet below, up to this point, most of the Clear Creek canon, through which the railroad mounts to this elevation, is a closely shut-in

winding gorge whose precipitous sides furnish a variety of scenery; a constant and pleasurable wonder to one who first makes the journey. Near Idaho Springs, however, the canon widens out into a valley over a mile long, in the centre of which lies the town, a very pretty place as seen from the low hills on the south. It is a clean, well-arranged city of about two thousand inhabitants and five hundred houses, built along the north and south banks of a small stream—the South Clerk Creek.

To the north of the valley, which here runs east and west, the mountains rise more abruptly and higher—thus protecting the town from inclement north winds—while the less precipitous mountains to the south allow a desirable long continuance of sun exposure.

The three hotels of the town, together with a restaurant and several boarding-houses, have entertained an average of about five hundred strangers during the summer months, not to mention many tourist parties which have come up from Denver just for a day's trip. This fact, together with the record of about a thousand baths given at the bath establishment at the springs during the past summer, gives a good idea of the summer popularity of this resort. There is no reason why this record should not extend through the remainder of the year and be trebled during the summer time, when the contemplated improvements of the springs and baths, and suitably attractive hotel accommodations for invalids in winter, are completed.

Those who have the requisite vigor and endurance to accomplish the same, can plan walking, fishing and sight-seeing excursions, which, with the baths and improvised or occasional amusements in town, may help to while away a considerable sojourn in this delightful locality and bracing climate.

THE MINERAL SPRINGS.

The discovery of the *Hot Springs* at Idaho was made in a curious way. There is quite an area of ground near the mouth of Soda Creek where a well sunk ten or twenty feet will reach hot mineral water. In 1859, in the days of the gold excitement, a miner, James Jack, "struck" hot water in a prospect hole, which was afterward enlarged and used as a bathing pool by gulch miners, prospectors, and adventurers. Afterwards, other sources and other kinds of water were discovered near by, but the popularity which these springs have acquired for medicinal virtues are due chiefly to two of the flows, viz.: the warm iron and soda spring, which is called the "Drinking Spring," and the Bath Spring, which is principally used for bathing purposes.

Apart from the main group, and below where Soda Creek empties into Clear Creek, is a cold saline spring, which Dr. Brummond says he has often prescribed for constipation with excellent results, the patients taking two goblets of the water, which is quite palatable, before breakfast and in the evening. There has been no analysis of the water of this last-mentioned spring.

It is estimated that all the hot water flowing from the different sources in the main group, if conducted into a trough a foot wide, would make a stream a foot deep moving as fast as a man walks. This gives an idea of the abundance of the flow. There is evidently hot water enough were it properly collected; and could it be done, the writer suspects other varieties would be discovered. Much as at Steamboat Springs, Colorado, where there is a great variety of mineral water, there seems to be at Idaho Springs a change in the geological formation of the mountain—a vein or ledge breaking out, by means of which these hot currents reach the surface from nature's labyrinth deep down in the earth.

The largest of these flows is from "the Well," which has been sunk twenty-five feet below the surface, and out of which the water is pumped in summer for use in one of the three bathing-houses there. The temperature of this water is 110° F. Another large flow is from the Bath Spring, used at present in the lower and newest of the bath-houses. The analysis of this, made by Dr. I. G. Pohle, of New York, is given below. The temperature is from 103° to 110° F. as the water flows into the bath.

ANALYSIS.

Carbonate of soda	52.81
Carbonate of lime	16.32
Carbonate of magnesia	4.94
Carbonate of iron	7.07
Sulphate of soda	50 34
Sulphate of magnesia	32.09
Chloride of sodium	7.13
Silicate of soda	6 99
Total	177.69

Gas: Carbonic acid.

There is another source near by from which similar water is obtained, but of a higher temperature, 120° F.

Further up the gulch and to the left is the *Drinking Spring*, which is an alkaline chalybeate water of evident value. The deposit from the water, as it flows away from a pool beside a rock and becomes colder, looks like the bicarbonate of iron, which must exist in unusual proportion. The gas that bubbles up with the water is probably carbonic acid, and the temperature of this water is 85° to 90° F. This water is much used for drinking, and has acquired considerable reputation for the relief of dyspepsia and for its salutary action on the kidneys.

Further up the valley and to the left, still more wonderful phases of this mineral spring formation

remain to be described. These are the *Cave* and the *Tunnel Springs*. The former is a warm pool—temp. .100° F.—at the bottom of a considerable excavation in the rock which forms the mountain side. A little house is built close to the entrance of the cave, where the bather can gradually cool off after the bath.

The Tunnel Spring is more remarkable. Here is an excavation directly into the rock at the base of the mountain to the extent of fifty or sixty feet in length, and eight feet wide and high. Partitions are built across this tunnel at twenty and forty feet and at the entrance. In the inner room a bathing pool is constructed large enough for one or two persons. There is quite a large flow of water through this basin, and its temperature is 105° to 110° F. The inner room is filled with an atmosphere about as hot as the water, and also saturated with medicinal vapors. Under these peculiar conditions we have a good imitation of the old Russian bath. The relaxation and cutaneous perspiration possible in this natural steam-vault can be carried to any desired extent, and much caution is needed in again returning to the outside atmosphere. A cold plunge or shower-bath after such treatment would act as an excellent prevention of "taking cold," by closing the pores and fortifying the skin against the sudden change of temperature in coming out of the tunnel.

The opinions of the local physicians as to the curative virtues of the medicinal water should be valuable in this connection. Dr. P. Brummond, as already stated, has often prescribed the lower spring water for constipation. He has also found good results from the use of the "drinking," or iron-soda water, in dyspepsia and in kidney disease (gravel), and in cystitis. The "hot tunnel" baths he has prescribed in conjunction with the internal use of salicylic acid or iodide of potassium for rheumatism, and been much pleased with the effect. He has noted good results likewise from the use of the "bath" spring water for eczema, taken internally as well as used by bathing.

Dr. William B. Hawkins, another resident physician, has kindly furnished the following notes of three patients who have used the waters, and his evidence seems to agree with what we would expect to result from their judicious use in gouty and rheumatic affections:

CASE I.—Mr. A. D., a resident of this place, thirty-seven years of age, inclined to stoutness and possessed of a gouty disposition and heredity, came to me in March, 1888, suffering from the usual symptoms of lithiasis or latent gout. In addition to remedies addressed to his digestive disturbances, I advised the systematic use of the alkaline mineral water internally, in conjunction with frequent alkaline baths (natural hot spring water). All the symptoms were promptly relieved, and though he had been long subject to similar attacks, none have occurred now for nearly a year, the mineral water having been continued quite regularly.

CASE II.—Mr. G. M. B., of St. Louis, came here in June, 1888, suffering from sub-acute rheumatism in both ankle-joints, which rendered locomotion very difficult, painful, and almost impossible. After three or four weeks' use of the hot baths, and the mineral water internally, he returned home greatly improved, being able to walk without the slightest difficulty.

CASE III.—Mr. A. D. J. came here in July, 1888, from Nebraska, a great sufferer from chronic rheumatism, nearly every joint in his body being more or less affected. He "camped out" in the neighborhood of the springs, relying exclusively upon the internal and external use of the alkaline water, and after a residence of about two months went away almost entirely relieved of all his disabling and painful joint symptoms.

In addition to the above-described cases, there are many people at present residents here who enthusiastically ascribe their nearly complete immunity from the recurrent attacks of rheumatism, to which formerly they were subject, to the regular use of our alkaline water.

Mr. Montague, the present owner of the hot springs, has seen several cases of periodical gout relieved in those who have come up to take a course of baths and to drink the water. Of course, the absence from convivial scenes and from over-indulgence, together with the exceedingly bracing atmosphere, are valuable aids to the mineral water in the relief of these cases.

However, the statement as to the cure of gout emphasizes a marked correspondence between Pohle's analysis of the Bath Spring water and that of the "Sprudel," at Carlsbad, in Bohemia, the fame of which for use in gout and kindred affections has become world-wide. The only essential difference between these two flows appears to be that the Carlsbad is hotter (169.5° F.) and it has a stronger element of soda, while Idaho Springs has a very much greater proportion of iron. As compared with the Carlsbad, the Idaho Springs water is less saline and purgative, but more tonic. It is undoubtedly a very valuable alkaline, saline, alterative, and tonic water.

Like Carlsbad, these waters should, and undoubtedly will, gain a reputation for the relief of diabetes, and of gastric catarrh, either alone or associated with disease of the liver. Prof. von Niemeyer especially recommended the Carlsbad waters for gastric catarrh. The writer would recommend the use of the Idaho Springs water for a very common condition, hyperæmia or engorgement of the liver, whether it be active or passive, with the suggestion that should drinking the water not prove laxative enough then in addition a hot sour lemonade be taken on retiring at night or rising in the morning. This plan, with the proper diet and the climbing of hills during the daytime, would be very likely to bring a rebellious liver "to terms." If it did not, and the patient continued to have too constipated bowels, the addition of a teaspoonful of Glauber's salts to

the early morning draught might be efficacious. This last addition would make the water as strong or stronger than the Carlsbad.

Looking for other correspondences among the noted springs abroad, we see a marked similarity between the Idaho Springs water and the Marienbad, situated in Bohemia, twenty-two miles south of Carlsbad. This, however, is a cold spring and very purgative. Otherwise the correspondence between the Idaho and Marienbad is even more marked, because of their chalybeate qualities, than between Idaho and Carlsbad springs.

Of the Marienbad waters a distinguished authority on mineral waters has said, what has also been claimed for the Idaho Springs water, that beside an increase in the excretion of urine, "the secretions of the mucous membranes are increased and perspiration is more free. The appetite and digestion usually improve under their use, and, owing to the presence of carbonic acid and iron, the prolonged use of the water does not prove as debilitating as otherwise would be anticipated."[1]

In the chalybeate qualities there are still more remarkable correspondences between the Idaho and the celebrated St. Moritz Springs in Switzerland.

The writer, when visiting the Maloya Valley, Switzerland, in the summer of '88, was surprised at the reputation the St. Moritz flow had acquired, considering the remarkable simplicity of the analysis (total ingredients, ten grains to the pint—*i. e.*, aside from the carbonate of iron contained). These springs have become the attractive centre of large hotels, where thousands yearly linger to drink the tonic waters. Maybe an American should not allow his wonder to be too demonstrative, because the Arkansas Hot Springs, with one-tenth as much mineral ingredients, has become quite as celebrated, and even the pure water of Waukesha has a continental reputation.

However, the St. Moritz is one of the best of Dr. Walton's group of foreign chalybeate waters—the Schwalbach and Pyrmont, in Germany, the Spa in Belgium, and the St. Moritz, in Switzerland. Nevertheless, the Idaho Springs contain three times as much carbonate of iron, and nearly three times as much carbonate and sulphate of soda as the St. Moritz flow, which latter has also the disadvantage of being a cold spring (49° F.).

The use, therefore, of the "Drinking Spring" water at Idaho Springs for anæmic conditions, chlorosis and convalescence from diseases attended with impoverished blood states, will naturally be suggested to every medical mind.

It will not be difficult for a physician to select a typical case that would be benefited by drinking this spring water, especially in such a bracing climate a mile and a third above sea level. In the opinion of the writer, a typical case would be a chlorotic young woman—probably with constipation and amenorrhœa, deficient muscular tone and lung capacity, feeble assimilation and languid nerves, with or without some gastric catarrh. How often the busy practitioner sees such a case, and wishes the needed iron could be so combined as to relieve and not increase the accompanying constipation. In the Idaho Springs iron water nature has accomplished the desired combination in the sulphate of soda present. The surrounding conditions are also best calculated to give renewed circulation of blood and vigor of muscle.

This water is chalybeate without being constipating; laxative without being depressing; alkaline, yet with an excess of carbonic acid; hot, yet agreeable to the taste.

In the drinking spring is almost an exact imitation of the celebrated Apollinaris Water, with the carbonate of iron, the silicate of soda, and a little sulphate of magnesia added. It can be taken with greater impunity than many simpler waters, because of its peculiar combination, the main effect to guard against being a tendency to congestion of the head from the excessive amount of iron.

If acid dyspepsia, with chronic catarrh of the stomach, is not relieved by its internal use, the addition of a little common salt to that which is drunk after meals may be serviceable.

As a bath the use of the hottest spring water can be recommended for chronic rheumatic swellings, the swelling or stiffness of joints, plethoric or impure blood conditions, especially if associated with any eczemas or chronic skin diseases. Besides in certain chronic diseases peculiar to women, the local use of the hot water at the bath would be invaluable—such as for leucorrhœa, subinvolution, or chronic uterine inflammations.

(To be concluded.)

[1] The Mineral Springs of the United States and Canada, etc. By George E. Walton, M.D. D. Appleton & Co., N. Y.

TWO RARE TUMORS OF THE BREAST.

I. Carcinoma in the Male Breast. II. Abscess simulating Carcinoma in the Female Breast.

By DUDLEY P. ALLEN, M.D.,
VISITING SURGEON TO LAKESIDE AND CHARITY HOSPITALS; CONSULTING SURGEON TO ST. ALEXIS HOSPITAL, OF CLEVELAND, OHIO.

Two rare cases of diseased mammæ have recently come under my attention.

Case I. was a carcinoma in the breast of a man, fifty years of age, with good family and personal history. No case of cancer had ever occurred in his family within his knowledge. I saw the man in February, 1889. About one year previously, while bathing, he had scratched his right breast. He put on a red flannel shirt, which caused much smarting

that night. This was the first time he noticed any trouble with the breast. For three months various salves were applied, and later a wash of carbolic acid was used. First the nipple became ulcerated, and the process has gradually extended until there is now a phagedenic ulcer four inches transversely by two and a half inches vertically, invading the region of the right breast. Scattered about the periphery of the ulcerating surface are nodules the size of a small pea and larger, appearing as hard masses on palpation, and many of them covered by reddish integument. This deposit of nodules also forms a line crossing the thorax from the right to the left mamma. The left mamma is enlarged, indurated, and discolored, but not ulcerated. It measures one inch vertically by two and a half inches transversely. The left nipple is retracted, as in a scirrhus. The glands of the left axilla are enlarged, one being the size of a hickory nut. From the ulcerating surface on the right side a line of induration extends under the border of the pectoralis major to the right axilla. By consent of the patient a small piece of tissue was removed from the indurated border of the ulcerating surface. It presented, under the microscope, the most typical appearance of carcinoma.

CASE II. was a chronic abscess of the breast simulating a carcinoma. Mrs. S., æt. forty-three years, has borne ten children. The first eight children had nursed both breasts.

At the birth of the ninth child the right breast gave a little trouble, and the nipple retracted so child could not nurse it. The tenth child, at the time of operating on this case (February 4, 1889), was about two years old, and had nursed on the left breast *twenty-two months*. No attempt had been made to nurse the right breast, since the retracted nipple rendered it impossible. The right breast secreted some milk, however, as was shown by its escaping from the right nipple while the left was being nursed.

In September, 1888, a lump was noticed in the right breast. There were occasional shooting pains in it, but they were infrequent, and there were none of the ordinary signs of any inflammatory disturbance. The increase in size was very gradual. When I saw the case in February, 1889, in company with Dr. A. J. Cook, I could feel in the right breast a tumor about the size of a large hen's egg, situated to the right of the nipple. The nipple was markedly retracted. The mass was dense; there was no redness of the integument, nor tenderness on firm pressure. I had been called to operate upon the case as one of "scirrhus" of the breast, and the appearance seeemed typical of this disease.

Upon carrying my first incision into the mass there escaped several ounces of thick, laudable pus, much to the surprise of all who witnessed the operation. Fortunately, the breast was not damaged by the incision.

Were I to see a similar case, I know of no means of examination which would distinguish it from a carcinoma of the breast with retracting nipple, save an exploratory incision. The fact that the retraction of the nipple occurred so early in the history of the case (viz., while nursing the child before the last) was doubtless not given sufficient weight. This fact was not elicited, however, until after the incision was made.

A CASE OF RATTLESNAKE BITE, SEEN TEN MINUTES AFTER THE ACCIDENT—RECOVERY.

BY W. M. MEMMINGER, M.D.,
OF CHARLESTON, S. C.

As it is not usual for a physician to see a case of this kind so soon after the infliction of the wound, and as the result of my treatment was so satisfactory, I take this opportunity of presenting the case to my colleagues in the profession.

The patient was a colored laborer of about thirty years of age. While engaged in cleaning some brushes away he was struck in the forefinger of the right hand, the fang of the snake entering the side of the finger, at about the middle of the last phalanx. Seeing that it was a rattlesnake which had bitten him he gave a cry for help, and ran toward some of his fellow-laborers, a distance of about fifty yards. By the time he had reached them he fell, in an unconscious condition. One of the men had the presence of mind to put a ligature tightly around the wounded man's arm, above the elbow, and a half pint of whiskey was poured down his throat; he was then brought immediately to my office—the whole time, as well as I can judge, not being ten minutes before he was presented to me.

The arm, by this time, was enormously swollen; whether from the ligature or from the poison, I do not know, but I think from the poison. The patient was completely unconscious; pulse, thirty to the minute; respiration slow; extremities cold; and involuntary evacuation of the bowels. To all appearances there was no hope, and I must say I was somewhat at a loss to know what to do. I made a free incision, down to the bone, through the wound, cutting both vein and artery of the finger; I then applied Esmarch's tourniquet, just below the shoulder. After having applied this, thinking that perhaps it might be well to try to drive as much blood out of the arm as possible, I applied Esmarch's elastic bandage, beginning from below the tourniquet and descending; this seemed to act well and bled the arm very thoroughly.

There are certain facts just here which I think are worthy of mention. The tissues through which I cut were almost black in color, and the blood extracted from this arm failed to coagulate. In all he bled about a quart. I also resorted to a method which I have seen recommended—that is, of injecting into some of the larger veins a solution of ammonia in water 1–3 : 20 minims every half hour; this I injected into the median basilic, twice during the first hour and afterward one after each collapse. The next theory I carried out was giving the patient the poison gradually.

In about an hour's time after he was brought in to me he had recovered almost entirely—so much so

that he was able to sit up and talk with his friends. I now tried the process of giving him the poison. I loosened the tourniquet; no sooner had I done this than he fell into an unconscious condition and apparently in as dangerous a state as before. The tourniquet was loosened for, I suppose, not more than three beats of the heart. This alarming and dangerous condition was caused, I presume from the effects of the poison, the effects of the whisky having worn off several times during the day, the man being perfectly sober in the intervals between the periods of collapses, produced by the slackening of the tourniquet. This process I repeated six times within seven hours, the patient rallying each time within an hour. At the end of the seventh hour the tourniquet was removed entirely, the wound dressed with boracic acid and the man removed to his quarters, partially delirious.

He was bitten on Saturday morning, and on Monday morning he walked to my office to have his finger dressed. The hand had a somewhat erysipelatous appearance and pained him considerably, but in no other way did he feel any bad effects.

Erysipelas did not set in, and in a few days he had completely recovered. The snake was killed a few minutes after the accident and proved to be a rattlesnake about two and one-half feet long.

HOSPITAL NOTES.

JEFFERSON MEDICAL COLLEGE.

SERVICE OF J. M. DA COSTA, M.D.

(Reported by E. P. HERSHEY, M.D., Clinical Assistant.)

HYSTERIA WITH PECULIAR SYMPTOMS.

November 22. K. J., æt. seventeen. Three years ago, antedating the beginning of menstruation, began to have peculiar seizures, supposed to be epileptiform. While standing she would suddenly become rigid, fall to the floor, and then have convulsive movements. One year ago, the case was treated as one of epilepsy, and under the bromides the attacks ceased. Four weeks ago she went into a state of seeming unconsciousness, lasting nearly two weeks. To all appearances she was unconscious of her surroundings; at times she became excited, and would make efforts to jump out of the window. She has at no time either bitten her tongue or fallen so as to injure herself. During the past two weeks the nature of the attacks has changed. Perfectly rational, she suddenly stares vacantly into space, the muscles of the face immovable, lips slightly parted, pupils dilated. The face has not lost its color. In a few minutes the head rotates to the left, followed almost instantly by the trunk; convulsive movements of the left hand then occur, followed by relaxation of all the muscles, the eyes close, and the head drops forward. All attempts to arouse her fail. Remaining in this condition for nearly five minutes, her eyes open and become fixed, the head slightly raised, the face assuming a peculiar look of pleasure—a condition of ecstasy. This gives way to an apparent faint, when she soon begins to mutter, at times humming, at others she remonstrates with those about her; she then attempts to escape, but being detained becomes rigid, but does not fall. The attitude assumed is one that makes those about her think she will lose her equilibrium, but she remains rigid. At times she recognizes those about her during the attacks, and almost in an instant she does not recognize her mother; when asked questions there is usually a meaningless smile upon her face, and she talks incoherently.

When the eyes are fixed, the reflexes are normal, and though the pupils are widely dilated they quickly contract when a bright light is brought before them.

Her menses are regular, though scanty. Has some pain during her sickness, but the attacks are not influenced at this period. There is slight tenderness along the lumbar vertebra. Pressure over the ovaries does not influence the attack, nor is there pain in this region. She states that she often has pain commencing in the lumbar vertebræ, going up the spine, and then to the left and right sides of the head. She has always been very emotional, is easily affected, and readily laughs and cries.

In this case there are three possibilities: Hysteria, epilepsy, and hystero-epilepsy. That it is a case of hysteria would appear from the fact that notwithstanding there were convulsions in the early history of the case, she has never had a spell while alone, and has never bitten the tongue. Were it a case of epilepsy, these striking negative results would be absent; and, too, in epilepsy the pupils are very slightly influenced by light, here they act normally. The whole *morale* of this girl shows the case to be one of hysteria rather than one of epilepsy. She is a healthy-looking girl, and has an elegant color. A case, therefore, of neurosis, the symptoms of which make it a curious one.

Treatment: ℞. Zinc. valerinat. gr. ij, four times a day. At night: ℞. Chloral hydrat. gr. x; sodii bromid. gr. xx.

Keep her quiet. See that she lies down three or four times a day. A diet largely of milk, nourishing, and not stimulating. In order to free the menstrual flow:

℞.—Globules of apiol āā gr. v.

Using six in the twenty-four hours before the time and during her sickness, at which time suspend the valerianate of zinc.

Two weeks later the patient was again presented before the clinic. The results of the treatment were striking. Her menses were no longer scant. No seizures from the time she was put under treatment. The question arose as to whether or not the treatment should be continued. In view of the marked improvement it was found advisable to continue it.

One month later the treatment was discontinued, but in a few days the patient stated that she had occasional feelings of approaching attacks, which soon wore off. Up to the present time April 1, 1889, she has had but four seizures, the last being March 15th. The valerianate of zinc is still continued.

MEDICAL PROGRESS.

Albumin in the Normal Urine.—In the discussion on the prognosis of albuminuria, at the last annual meeting of the British Medical Association, reported in the *British Medical Journal* of August 24th, DR. GEORGE JOHNSON said that from the results of numerous and careful obser-

vations, he was convinced that no albumin existed in normal urine—in other words, that albuminuria was always pathological. The most delicate and entirely trustworthy test for minute quantities of albumin is a saturated solution of picric acid, with the subsequent application of heat. Any opalescence resulting from the addition of picric acid, which is increased and not dissolved by heat, is certainly albumin, except in the very rare case of an immediate separation of uric acid in sufficient amount to render the mixture cloudy. In such cases the crystals of uric acid may be seen with the microscope. Picric acid causes no opalescence in normal urine. It does not precipitate mucin, as has sometimes been asserted; but when combined with acetic or citric acid, the mucin which is precipitated by either of these acids is rendered more conspicuous by the yellow picric acid.

The test for albumin which in delicacy comes nearest to picric acid is nitric acid at the bottom of a column of cold urine. Those practitioners who boil the urine before adding nitric acid must often fail to detect a trace of albumin which might readily be detected by nitric acid in the cold urine. A slight trace of albumin is apt to be decomposed by the addition of nitric acid to the boiling urine.

A comparison of the nitric acid and picric acid tests may most satisfactorily be made by gradually diluting a specimen of albuminous urine. At a certain stage of diluting it will be found that while picric acid gives an instantaneous opalescence, the nitric acid test forms an opalescence at the junction of the two liquids only after some minutes. Then, in urine yet further diluted, the picric acid, with the subsequent application of heat, gives a decided indication of albumin which the most careful testing with nitric acid fails to show.

He had so often compared these two tests that he can now tell at once whether a trace of albumin, which is clearly shown by picric acid, is so small that nitric acid either fails to indicate it or it does so only doubtfully after the mixed liquids have been allowed to stand for some minutes.

Another important use of picric acid is in estimating the amount of albumin by Esbach's simple but accurate quantitative process. Again, picric acid is a more delicate and trustworthy test for peptones than Fehling's solution, the precipitated peptones being redissolved by heat below the boiling-point. It is often stated that peptonuria is of common occurrence. As to this, he said that in carefully testing many hundred specimens of urine he had never met with peptones, except in small quantity, associated with an abundance of albumin.

The separation of peptones from albumin is easily effected by passing the boiling mixture of urine and picric acid through a previously warmed filter. The coagulated albumin remains on the filter while the dissolved peptones pass through and are precipitated on cooling.

Once more, the picric acid and potash test for glucose, while it is equal to any other for accuracy of result, surpasses all others by its readiness of application and facility of working. One especial advantage over the copper test is that the presence of albumin in no wise interferes with the action of the picric acid and potash quantitative test for sugar. In several instances he had known the reducing action of uric acid and urates upon Fehling's solution mistaken for an indication of glucose.

The Prognosis of Albuminuria.—DR. JOHNSON, after discussing at length the opinion of various writers upon the subject of the prognosis of albuminuria, draws the following conclusions:

1. The presence of albumin in the urine, though small in amount and occasionally intermittent, is always pathological.

2. The practice of testing the urine in all cases of ailments, even the most trivial—the importance of which I have for many years past insisted upon—has led to the detection of albuminuria in many youths and adolescents, who are especially liable to be exposed to the commonest of its exciting causes, namely, cold and wet and over-fatigue, and who have not lived long enough for the ultimate evil results of a neglected albuminuria to have become developed.

3. The albuminuria, whether intermittent or persistent, of persons apparently in good health has no such special features as to require it to be designated by such misleading terms as "physiological," "functional," "cyclical," and "the albuminuria of adolescents." The last term is especially inappropriate, since the condition is of most common occurrence in both sexes and at all periods of life, from childhood to extreme old age.

4. In almost every instance these cases of albuminuria may, by a careful inquiry, be traced back to some recognized exciting cause.

5. Nearly all cases of acute nephritis pass through the stage of intermittent albuminuria in their progress toward convalescence; and, on the other hand, the majority of cases of intermittent albuminuria may be traced back to a more or less remote attack of acute nephritis.

6. While, on the other hand, intermittent albuminuria—even though it may have existed for years—may be looked upon as a curable condition if only its exciting causes can be ascertained, avoided, and counteracted by suitable dietetic, medicinal, and hygienic means; on the other hand, the neglect of such means may convert an intermittent into a persistent albuminuria; and a persistent albuminuria, although for many years it may be unattended by symptoms of disordered health, ultimately results in a fatal degeneration of the kidneys.

7. Since it is notorious that albumin, even to a very large amount, may exist in the urine of persons who are apparently in perfect health, it is obvious that the urine of every patient, no matter how apparently trivial his ailment, and the urine of every applicant for life assurance, no matter how robust his appearance, should be tested for albumin.

8. For many years past the fact that albumin may be abundantly present at one period of the twenty-four hours, and entirely absent at another has been publicly demonstrated, and ought to be generally known. It is, therefore, necessary to test the urine, not only after rest in bed and before breakfast, but also after food and exercise.—*British Medical Journal*, Aug. 24, 1889.

Treatment of Burns with Iodoform.—DR. SCHIFF, of Vienna, speaks most highly of Dr. Mosetig's method of treating burns with iodoform. Apart from iodoform quickly easing the pain of the burn, it also effects rapid

healing. The blisters should be removed and the wound washed lightly with a tampon of cotton dipped in a 0.5 per cent. solution of salt and water, then several layers of iodoform gauze should be laid on the wound, upon this a piece of rubber, then cotton, and the whole secured with a roller bandage. If the discharge soils the bandage, it and the cotton may be changed, but the iodoform gauze should not be removed until the end of the first week. For burns of the face, Mosetig recommends a salve of iodoform (one to twenty). The face should also be covered with a mask of gutta-percha. Schiff has treated 109 cases of burns in this way; the majority healed quickly; many of them were both severe and extensive. No toxic symptoms were observed.—*Wiener med. Presse*, August 18, 1889.

Antipyrin in Menstrual Colic.—Antipyrin has, of late, been given in cases of uterine colic and cramps, occurring during menstruation, with excellent results. The drug is administered in the form of a clysma in a single thirty-grain dose. The sedative action is observed in about half an hour; in some cases a repetition of the dose is called for in twelve hours. DR. WINDELSCHMIDT has used this treatment in a number of cases, and always with satisfactory results. Usually a slight hypnotic action seemed to be also exerted by the drug. Other unpleasant accompanying symptoms, aside from sweating and slight ischuria, were not observed.—*Münchener med. Wochenschrift*, August 20, 1889.

Suppositories for Endometritis.—TERRIER, in the *Revue Thèr. Méd.-Chirurg.*, August 1:

℞.—Powdered iodoform . . . ʒijss.
Tragacanth . . . . . grs. viij.
Glycerine } . . . . . q. s.—M.
Distilled water }
For ten suppositories.

These suppositories should be made in the form of crayons, about the size of a nitrate of silver point, such as is used for cauterizing. Resorcin or salol may be used in place of iodoform in the formula, the same quantity being admissible. If, however, bichloride is preferred, the formula should be altered as follows:

℞.—Sublimate of mercury . . . grs. viij.
Powdered chalk . . . . ʒvjss.
Tragacanth . . . . . grs. xxiv.
Glycerine } . . . . . q. s.—M.
Water }
For 50 suppositories.

These suppositories should be placed in the cavity of the uterus after the vagina has been thoroughly washed and disinfected with sublimate solution. A tampon of iodoform gauze may be placed in the vagina.

Treatment of Retention of Urine from Prostatic Enlargement.—In the Medical Section of the last meeting of the British Medical Association, reported in the *British Medical Journal* of August 24th, MR. A. F. MCGILL opened a discussion upon the treatment of retention of urine from prostatic enlargement. He advocated the following propositions—(1) That prostatic enlargements which give rise to urinary symptoms are intra-vesical, and not rectal. (2) That retention is caused by a valve-like action of the intra-vesical prostate, the urethral orifice being closed more or less completely by the contraction of the bladder on its contents. (3) That in many cases self-catheterization is the only treatment required. (4) That when the catheter treatment fails, or is unavailable, more radical measures are necessary. (5) That this treatment, to be effectual, should (*a*) for a time thoroughly drain the bladder, and (*β*) permanently remove the cause of the obstruction. (6) That these two indications are best fulfilled by a supra-pubic rather than by a urethral or perineal operation. The supra-pubic operation is preferable (*a*) because it is more generally applicable, (*b*) because it can be performed with greater precision and completed with greater certainty, (*c*) because it insures complete and most efficient drainage, (*d*) because it is equally safe. Of ten patients upon whom the speaker had operated eight had continued well, only one having required the passage of a catheter, and that only after excessive drinking. In one case, owing to the extreme hardness of the prostate, the operation was unsatisfactorily completed; in another there was temporary relief, with death at the end of ten months.

MR. EDWARD ATKINSON said he had performed supra-pubic prostatectomy in five cases. Of these, one had died, and the remaining four were well—had good control over the bladder, did not require to micturate more than six to ten times in the twenty-four hours, and were enjoying fair comfort.

MR. REGINALD HARRISON referred briefly to some cases of advanced prostatic obstruction which he had treated by perineal prostatotomy, which he thought was specially applicable to those instances where obstruction was the prominent and most distressing symptom. He concluded his observations by a reference to the importance of the early treatment of prostatic enlargement by mechanical means.

MR. BRUCE CLARKE stated that the obstruction was due mainly to two causes: (1) the growth of the prostate into the urethra, and (2) into the bladder; and both of these must be relieved. He had had eleven prostatic cases under his care, in which some form of operation was required. So far his plan of treatment had been to make a perineal incision first, and examine the bladder; if necessary, incise the floor of the prostate; then one could ascertain exactly what needed to be done, and perform a suprapubic operation afterward, if necessary. He had done this in two cases with the best results.

DR. WARD COUSINS said he had performed two operations for prostatic retention and calculus. Both cases were old men laboring under intense suffering. He enucleated some masses around the neck of the bladder, which proved to be cancerous. Both cases were for a time relieved. He though Mr. McGill's operation would be the method practised in the future for cases in which catheterization was impossible from pain and mechanical difficulty. The essential treatment consisted in the timely use of the catheter.

MR. MACEWEN wished to say that after hearing Mr. McGill's paper, seeing his patients in the Leeds Infirmary and the specimens, he had upon this evidence become a convert to the suprapubic removal of the prostate, as it removed the pathological cause of the difficulty; and he would put the operation in practice on the earliest suitable opportunity.

MR. BENNETT MAY agreed that it is the intra-vesical growth which causes the obstruction and retention, and further, when retention is complete and permanent, that it is collar enlargement; with partial retention, but great irritability, a pedunculated middle lobe. He believed that for drainage the suprapubic is inferior to perineal cystotomy, but he regarded formal removal of any portion of the prostate by the perineal route as an impracticable proceeding in most cases. He thought Mr. McGill's operation should be done before the patient is much exhausted. In such cases median perineal drainage might be the more prudent course.

Mr. Jordan Lloyd, Professor Trendelenberg, and others also spoke, after which Mr. McGill replied.

Anthrarobin.—Anthrarobin, a drug which not long ago was looked upon with much favor by dermatologists, is fast losing its initial reputation. At the last meeting of the dermatologists in Berlin, reported in the *Deutsche medicinische Wochenschrift* of August 22d, DR. O. ROSENTHAL brought the subject of the utility of the drug up for discussion. Its condemnation was almost unanimous. True, it does exert a beneficial action in psoriasis, pityriasis, and herpes, but this action is so slight and so very slow that it is usually lost sight of. Then, again, the accompanying symptoms produced by the drug are far from pleasant, especially from a cosmetic point of view, as by its use the nails of the patient assume a violet color, and the hair takes a strikingly red hue. The patient's linen will also be ornamented with deep violet stains.

DR. BEHREND, in the discussion, stood up for the drug, and said its action entirely depended upon the manner in which it was used. Its action is much intensified when used in conjunction with soap. Anthrarobin is tolerated in many cases where chrysarobin is not. Again, anthrarobin never produces dermatitis or conjunctivitis, as in many instances chrysarobin does.

DR. KÖBNER had used anthrarobin in many cases of skin diseases, also in twenty-five cases of psoriasis. His results were far from satisfactory. He considers that the drug can in no way compete with either chrysarobin or pyrogallic acid. In psoriasis its beneficial action was only noticeable when combined with soap, and in all cases the scales had to be removed mechanically. In a few cases of superficial mycosis tonsurans the drug produced tolerably rapid healing, but its use frequently occasioned a burning sensation which lasted for some time, and in one case it even caused exfoliation of the skin. The stains on linen produced by it cannot be removed by even washing with soda, soap, and water.

Treatment of Chronic Catarrh of the Bladder.—DR. L. FREY, in the *Centralbl. für Chirurg.* of August 17th, claims that iodoform is especially suited for the treatment of chronic catarrh of the bladder, on account of its antiseptic, analgesic, and deodorizing properties.

The bladder should first be cleansed by a douche of warm water, and then a tablespoonful of the following, in a pint of warm water, should be injected into it.

R.—Iodoform	50 parts.
Glycerine	40 "
Distilled water	10 "
Tragacanth	¼ part.—M.

These injections should be repeated every third day. Three or four will usually effect a complete cure.

Dr. Mosetig-Moorhof has treated twenty-three cases in this way, all of which were cured. No symptoms of intoxication from the drug were observed.

Arrack in Diphtheria.—DR. ROUGE, in the *Deutsche med. Wochenschr.*, No. 29, strongly advocates the use of arrack in diphtheria. The local treatment consists merely in washing the mouth with lime-water. The dose of the liquor varies from a half-teaspoonful to one tablespoonful every two hours, according to the age of the patient. Dr. Rouge's intention is always to give a sufficient quantity so that a slight intoxication will be observable at the end of each day. Fever does not contraindicate the use of the liquor. Rouge reports forty successful cases treated in this manner. The duration of the disease was also considerably shortened, being on an average only eight days.

Phosphorus in the Treatment of Rickets.—The use of phosphorus in rickets, so much vaunted by Kassowitz and others a couple of years ago, has not, we believe, found much favor in this country. A very extensive trial of the remedy has recently been concluded by DR. L. B. MANDELSTAM, of Kazan, who publishes the results in *Vratch*. These experiments extended over a period of nearly three years, and the number of patients upon whom the phosphorus was tried was 450, their ages running from three months to four years. Of this number, however, 234 were excluded from the statistics, either because they did not take the phosphorus long enough, or in the proper way, or because the disease in them was not sufficiently pronounced to make the experiment a satisfactory one.

Of the remaining 216 children, 120 were cured, 43 were markedly benefited, in 30 no improvement was noted, and in the remaining 23 the treatment was discontinued on account of some intercurrent disease. The remedy was given dissolved in cod-liver oil, in the proportion of one part to ten thousand of oil, of which a teaspoonful was given once or twice a day. When it was not deemed advisable to give cod-liver oil, the remedy was administered, after the formula of Kassowitz, in a mixture composed of $\frac{1}{100}$th part of phosphorus, 15 parts each of gum arabic and sugar, 30 parts of almond oil, and 40 parts of distilled water. Dose, a teaspoonful once or twice a day. No other remedy was employed, except when diarrhœa was present, and then an attempt was made to cure this before giving the phosphorus.

The following are the conclusions which the author feels himself justified in formulating as a result of these experiments:

1. Clinical observation justifies fully the employment of phosphorus in rickets.

2. Phosphorus acts better, more quickly, and with greater certainty than any other remedies.

3. This drug, when given in small doses, even for long periods of time, is well borne by children, and causes in them no unpleasant effects.

4. Phosphorus is especially efficacious in controlling the nervous manifestations of rickets.

5. Periodical measurements and weighing of the children, as well as observation of the osseous structures, show that the disease is actually arrested in its course

and cured, in the great majority of cases, under the influence of phosphorus.

Another trial of the same remedy was made by Dr. Shabanova, whose report is also printed in *Vratch*. She treated 105 patients, and obtained perfectly satisfactory results in 77. In 22 an improvement was noted, and in 6 cases there was an aggravation of the disease while the treatment was being continued. The first effects of the remedy were seen in an improvement in the nervous symptoms, and later, in favorable cases, a change for the better was seen in the general health, and in the condition of the bones and muscles.—*Medical Record*, August 31, 1889.

Treatment of Dilatation of the Stomach.—The following method of treatment for chronic dilatation of the stomach is advocated by DR. KLEMPERER: The stomach should daily be washed with a small quantity of water, and a most careful diet enforced. As the stomach absorbs little or nothing while in this condition, it is necessary to give food which can easily be absorbed by the intestines. Hydrocarbons in the form of sugar of grapes, and fats in the form of cream, are especially valuable. Bread and butter may also be allowed. This hygienic treatment should be augmented by electricity and massage of the stomach.—*Revue de Thér. Méd.-Chirurg.*, August 1, 1889.

Dressing for the Umbilical Cord.—DR. CULLINGWORTH writes to the *British Medical Record* of August 24th that he has found starch powder to be the best dressing for the cord before its separation. It is far superior even to finely powdered boric acid; for while with the former dressing the cord will fall off in four or five days, with the latter it will frequently not do so for eight days.

Scraping out of Soft Chancres.—DR. OSCAR V. PETERSON, in *Vratch*, says that, in the course of the last eighteen months, he has treated 120 cases of soft chancre by means of scraping out after the following rules: Having cleansed the ulcer and surrounding skin with a corrosive sublimate or carbolic solution, he wipes the parts with a piece of cotton-wool soaked in ether, and then treats the chancroid ulcer with a sharp spoon, exactly in the same way as if it were a lupoid or an ordinary atonic one. The procedure over, he dresses the raw surface with iodoform powder and gauze. To make the operation painless, he previously injects under the skin a two-per cent. solution of hydrochlorate of cocaine. In eight or ten minutes anæsthesia is complete. In simple cases the ulcer cicatrizes, on an average, in 9.9 days. In 6 out of 120 cases healing was complete in three days, and in 25 in five days. In anæmic or alcoholic patients, however, cicatrization is not complete before the twenty-second or even the twenty-fifth day.

The author adds that, in 2,953 cases of soft chancre admitted during the period 1881–'87, the average stay in the hospital amounted to 27.5 days. In 1888, however, when the new method was resorted to, the average figure did not surpass 20.7. The percentage of complicated cases varied in the former category between 50.5 and 70.3, in the latter was equal to 62.1.

As to other methods of treating soft chancres, Dr. Peterson eulogizes painting with pure tincture of iodine, which is said to give best results in small-sized ulcers of recent origin, but sometimes causes local irritation; and excision of the ulcer and adjacent skin, with subsequent application of sutures. The wound heals per primam in three days.

The method, however, is painful, and in some cases impracticable (for instance, when the ulcer is situated on the glans penis).—*Journal of Cutaneous and Genito-Urinary Diseases*, September, 1889.

Cinchonism and Means of Preventing it.—DR. COGLITORE, in the *London Medical Recorder* of August 20th, after enumerating the principal symptoms of poisoning by quinine, says that in cases of toxæmia no good is obtained from various other remedies employed as substitutes for quinine (arsenic, salicin, eucalyptus, etc.). He finds that quinine is always well borne if given with ergotin and opium. This is his formula:

℞.—Sulphate of quinine . . . grs. xij.
Bonjeau's ergotin . . . . " v.
Opium . . . . . gr. j.—M.

Make into three powders, given at intervals of one hour.

Given in this manner, quinine succeeds in the gravest cases, and gives rise to no symptoms of cinchonism.

The Thermo-cautery in Mastoid Periostitis.—DR. E. MÉNIÈRE, in the *Centralblt. für Chirurgie*, advises the use of the thermo-cautery in periostitis of the mastoid process in place of the method of incising the skin, as advocated by Wilde. The affection frequently follows both acute as well as chronic otitis of the middle ear, and will be recognized as a most painful swelling back of the ear. An incision made with the thermo-cautery is superior to the old method of treatment for the following reasons: First, there is no bleeding; second, no anæsthetic is necessary; and third, the danger of infection is avoided. Ménière has successfully treated fifty-six cases in this way, in eleven of which the disease was primary. Should the opening of the mastoid process subsequently be necessary, the wound produced by the thermo-cautery may be enlarged and the bone opened through it.

Regarding the latter operation, RICARD, in the *Gaz. des Hôpitaux*, No. 23, 1889, discards all trephining instruments, and advocates the use of hammer and chisel. He also claims that better results will be obtained if the anterior portion of the process be opened into instead of the posterior. The skin should, therefore, be dissected away from the back toward the front.

Chloralamid.—The new hypnotic chloralamid seems to be still holding its place and keeping up its initial reputation on the Continent at least. DR. J. HAGEMANN, in *Berliner klin. Woch.*, of August 19th, gives a detailed history of fifteen cases in which the drug was used. These included cases of ischias, tabes, neuralgia, hysteria, aortic and mitral insufficiency, aortic aneurism, aortic stenosis, phthisis, anæmia, arthritis, syphilitic brain trouble, and lead poisoning. In almost every instance the drug acted like a charm; in one only, the case of hysteria, was its hypnotic action almost entirely absent; in one or two others its action was variable. Among the points in favor of chloralamid, Hagemann cites the absence of influence upon the circulation, kidneys, and stomach. Also, that in no case was there any symptom of the drug becoming a habit.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, SEPTEMBER 14, 1889.

HEALING OF ASEPTIC BONE CAVITIES.

As is recognized by every surgeon, the healing of the cavities of greater or less size, left after the removal of tuberculous or osteomyelitic disease of the bones, is generally tedious and often very unsatisfactory. The conditions for healing are less favorable than in almost any other wounds; the walls are rigid and cannot collapse as do those of an abscess, and often the soft tissues cannot come in contact with the floor of the cavity and thus promote a speedier union. Before the introduction of antiseptic and aseptic surgery, operations on the bones were not only attended with a large mortality, but when the patient escaped the more serious complications there was still a long period of suppuration, with its drain upon the system. This has now been changed, in a very great degree, by the careful application of antiseptic principles. It is now quite possible to secure the healing of extensive bone cavities or bone defects in a perfectly smooth manner, without any febrile excitement or a single drop of pus. This healing is effected by the formation of a mass of granulations, which becomes converted into reparative tissue rather than into pus, but at best the process is tedious and defective.

Attempts have been made by different surgeons to procure speedier and more perfect results, and with considerable success. DR. NEUBER, of Kiel, some years ago introduced the method of implantation of skin flaps, after chiselling or gouging the bone sufficiently to allow the soft parts to be brought into contact with the floor of the cavity. These flaps were fastened securely into position with bone nails, and in many cases primary union was effected; but there are several serious objections to the method: 1st. There is unnecessary removal of healthy bone required, in order to allow the implantation of the flaps. 2d. The flaps are liable to slough and leave defects which require a long time to heal; and, 3d. An irregularity in the surface of the limb will be left, which is undesirable. The method, however, is useful, and has been employed considerably.

The attempt has also been made by SCHEDE and others to secure healing under an aseptic moist blood-clot, and exceedingly favorable results have been obtained. The objections to the method are: 1st. It causes an unnecessary loss of blood, which, in some cases, would be dangerous. 2d. It leaves a collection of fluid which forms an admirable culture field for pathogenic microbes. 3d. It transgresses an almost inviolable precept of surgery—that all collections of blood and blood-clots must be removed from wound cavities.

DR. SENN (*The American Journal of the Medical Sciences*, September, 1889) conceived the idea of substituting aseptic and antiseptic decalcified bone-chips for the blod-clot, as they are absorbable, firm, and form a good scaffold upon which the granulations can be supported. With his usual industry he made numerous experiments upon dogs, before applying the method to man. The results of his experimental work proving satisfactory, the procedure was applied to patients with exceedingly favorable results. In operations upon the skull, it was found that a decalcified, aseptic bone-disk, fitted tightly into the trephine opening, not only promptly arrested hemorrhage from the margins of the bone, and formed a means of preventing adhesion between the external parts and the dura mater, but being gradually absorbed, a mass of granulations took its place, and the defect was closed either by bone or by a dense cicatricial tissue. It is recommended that the disk shall have a number of perforations in it, both for the purpose of drainage, and to allow granulations more easily to penetrate it. For the healing of bone cavities, chips of decalcified bone are used, after thorough disinfection of the cavity and the dusting of both the bone chips and the cavity with iodoform. The results claimed are rapid healing under one or two dressings, with entire

restoration of the continuity of the bone. Senn holds that antiseptic decalcified bone is the best substitute for living bone-grafts in the restoration of a loss of substance in bone, and that in the treatment of bone cavities it is preferable to Schede's blood-clot, as it is not only perfectly aseptic, but at the same time also a strongly antiseptic substance. Implantation of a disk or plate of antiseptic decalcified bone into a cranial defect may be relied upon as a hæmostatic measure in arresting bleeding from the vessels of the diploë; it constitutes a good temporary substitute for the lost portions of the cranium; it prevents the direct union of the brain or its envelopes with the pericranium; and, finally, it furnishes the most favorable condition for the production of new bone from the margins, and closure of the remaining defect by a firm and unyielding membrane. The packing of an aseptic bone cavity with chips of antiseptic, decalcified bone guards against unnecessary loss of blood, and exerts a potent influence in the prevention of infection by pus microbes that might have remained upon the surface of the wound or in the tissues. Capillary drainage by an absorbable drain should be established after implantation, for the purpose of preventing the accumulation of more blood in the wound than is necessary to form a temporary cement substance between the bone-chips, and between the contents of the cavity and the surrounding tissues. In the treatment of an aseptic bone cavity by implantation of chips of antiseptic decalcified bone, the packing answers the purpose of an antiseptic tampon and furnishes the best medium for the growth and development of the tissue resulting from the regenerative process initiated by the trauma. Secondary implantation can be successfully practised in the treatment of a suppurating bone cavity after suppuration has ceased, and the cavity can be transformed into the same favorable conditions for healing as an aseptic wound.

LITERARY PIRACY.

OUR attention has just been called to the most glaring example of literary theft that it has ever been our misfortune to be called upon to expose. Our esteemed contemporary, *The Lancet*, in its issues of May 18th and June 22d, contains a lengthy paper on "The History and Use of Anæsthetics in Midwifery. By Frederick W. Allwright, M. D., L.R.C.S.I.," which is taken bodily, in the most barefaced manner, from Dr. J. C. Reeve's chapter on "Anæsthetics in Obstetrics," in the first volume of Hirst's *American System of Obstetrics* (Philadelphia, 1888). Dr. Allwright—he would be more appropriately named Allwrong—has not added a single original sentence to the lengthy paper as it appears in *The Lancet*, although he has gone to the trouble to substitute here and there a synonym, or to invert the arrangement of words. We trust that the editor of *The Lancet*, who has been the innocent victim of this gross piracy, will give it the fullest publicity, so that, the true character of its author being exposed to public gaze in his own country, he will cease to be a source of possible discredit, through his devious methods, to the community in which he lives.

AT Boston, on Tuesday, Wednesday, and Thursday of next week, two of the National Special Societies will hold their annual meetings. The American Gynecological Society will meet at the Institute of Technology, under the presidency of Dr. H. P. C. Wilson, of Baltimore, and the programme contains a large number of most attractive titles.

The American Orthopedic Association will meet in the adjacent building of the Natural History Society, under the presidency of Dr. E. H. Bradford, of Boston, who, on taking the chair, will deliver an address on "American Orthopedics." A number of papers are on the programme, and on Wednesday there will be a very full discussion of the treatment of hip-disease, with a view to formulating the opinions of the members.

THE Southern Surgical and Gynecological Association will meet at Nashville, on November 12th, 13th, and 14th, and has issued a very full preliminary programme and a general invitation to the profession to attend the sessions. Dr. Hunter McGuire, of Richmond, is President for the year.

THE American Public Health Association will hold its next annual meeting at Brooklyn, N. Y., October 22, 23, 24, and 25, 1889. This Association comprises over eight hundred members, all devoted, officially or otherwise, to its declared purpose—the advancement of sanitary science and the promotion of organizations and measures for the practical application of public hygiene.

With the hope of still further promoting its objects, it is proposed, at the forthcoming meeting, to provide an exhibition of everything available adapted

to the promotion of health. The exhibits will be classified under nine divisions, as follows: the dwelling, schools and education, factories and workshops, clothing and dress, food, sanitary engineering, public health administration in cities and towns, the laboratory, Red Cross.

The Exhibition will be held in the hall at the northwest corner of Fulton and Pineapple Streets, one block from the Brooklyn Institute, where the sessions of the Association will be held. It will be opened to the public without charge on October 22d, at 1 P. M., and will continue open until December 1st.

Applications for space may be made to any member of the Committee on Exhibits, accompanied with details as to name and character of article proposed, space required, etc.

At the close of the Exhibition the Association will award diplomas to exhibitors of specially meritorious articles based upon the judgment of experts.

AN Army Medical Board will be convened in New York City, on October 1, 1889, for the examination of such persons as may be properly invited to present themselves before it as candidates for appointment in the Medical Corps of the Army. Application for an invitation should be addressed to the Secretary of War, stating date and place of birth, place and State of permanent residence, and accompanied by certificates, based on personal acquaintance, from at least two persons of repute, as to citizenship, character, and moral habits; testimonials as to professional standing from the professors of the medical college from which the applicant graduated, are also desirable. The candidate must be between twenty-one and twenty-eight years of age, and a graduate from a regular medical college, evidence of which, his diploma, must be submitted to the Board.

Further information regarding the examinations and their nature may be obtained by addressing the Surgeon-General, U. S. Army, Washington. There are at present nine vacancies in the Medical Corps in the grade of Assistant Surgeon.

DR. JOHN T. BANKS, of Dublin, has just been made a Knight Commander of the Bath, Civil Division, and, therefore, becomes Sir John Banks, K.C.B. Sir John is Physician in Ordinary to the Queen in Ireland, and Regius Professor of Medicine in the University of Dublin.

THE Asylum for the Insane in Newcastle County, Delaware, will presently, by purchase, become a State institution. Dr. D. A. Harrison, who has been the resident physician at the St. Johnsland Branch of the King's County Lunatic Asylum, has been invited to become the Medical Superintendent.

IN Belgium, all passenger trains are required by law to have a box of surgical appliances, called a *boite de secours*, containing many of the articles that are first called for in emergencies; a few short and plainly printed explanations accompany each package. In this land of magnificent distances, the indications for provisions against accident would seem much stronger than in a compact little kingdom like Belgium.

THE British profession has suffered another severe loss in the death of DR. SAMUEL O. HABERSHON, which occurred at his residence in London, on the 22d ult., aged sixty-four years. He succumbed to gastric disease accompanied by hæmatemesis—one of a class of affections which he did so much to elucidate. He was well known in this country by his works on the *Diseases of the Alimentary Canal*, which passed through three editions; *On Diseases of the Stomach, the Varieties of Dyspepsia; On Some Diseases of the Liver;* and *On the Pathology of the Pneumogastric Nerve*. He was a careful and painstaking observer, possessed of extensive practical knowledge; to these qualities were added high principle, rectitude of conduct, and sterling friendship, which gained for him honor and respect throughout a long career.

SOCIETY PROCEEDINGS.

GYNECOLOGICAL SOCIETY OF CHICAGO.

Stated Meeting, March 15, 1889.

THE PRESIDENT, CHARLES T. PARKES, M.D., IN THE CHAIR.

(Continued from page 275)

DR. BAYARD HOLMES made some remarks

ON THE RELATION OF BACTERIA TO PUERPERAL ECLAMPSIA.

It is well known that the subcutaneous injection of the urine of the healthy does not result in symptoms of uræmic poisoning, while these symptoms are exactly simulated by the injection of nephritic urine. The demonstration of acute nephritis in fatal cases of puerperal uræmic convulsions is not wanting. The bacterial origin of many other cases of acute nephritis is most emphatically de-

monstrated (Babes: *Bact. untersuch u. septische Processe*, etc., Leipzig, 1869). Bacteria have been demonstrated in some cases of uræmia. On no other supposition or theory have uræmic convulsions been satisfactorily explained. A toxæmia is conceded by all to be the prime condition of the disease. The normal constituents of the urine do not produce this toxæmia; the products of nephritic urine do produce it. Nephritis is usually, if not always, present. This nephritis is sometimes, if not always, due to bacterial thrombosis or embolism. This is the only adequate cause which has up to the present time been demonstrated in any case. It is in perfect accord with the origin of nephritis under other circumstances.

As there must in all cases be a point of entrance of the bacteria and diminished local resistance, we may be asked to go a step further and demonstrate these. The point of entrance is probably the intestinal tract. The low state of vitality which is manifest in many pregnant women, living after the manner dictated by modern civilization, results in such a low state of general resistance that teeth are invaded and abscesses appear elsewhere. Mechanical constipation produces in the intestinal tract points of arrested circulation or pressure atrophy where invasion takes place into the lymphatics of the mesentery. These bacteria do not need to be pathogenic under ordinary circumstances. They circulate freely in the blood until they come to the kidneys and other organs, where mechanical capillary stasis is present from the pressure of the enlarged uterus, assisted, perhaps, by improper dress. Under such circumstances, otherwise harmless saprophytic bacteria multiply in the non-resisting but still living tissues of the kidney, and the products of their growth produce coagulation-necrosis and all the less marked appearances of nephritis. The extent of these changes need not correspond to the severity of the symptoms. In case the infection produces a very toxic ptomaine, the lesion may be only just enough to prevent its rapid elimination; while, in case the ptomaine is less toxic, the symptoms may be trivial until the suppression of urine is almost complete.

DR. DANIEL T. NELSON then spoke on the

DIAGNOSIS AND PROGNOSIS OF PUERPERAL ECLAMPSIA.

Puerperal eclampsia is an acute epilepsy in a pregnant woman, due to an acute anæmia, rarely a hyperæmia, of the brain, produced by poisons circulating in the blood, such as urea, cholesterin, and the like, produced by defective excretion by the kidneys, intestines, and skin. The disease occurs more frequently in first pregnancies. The pregnant uterus pressing upon the ureters tends to narrow their calibre and prevent the discharge of urine into the bladder; or the tissues about the uterus are unyielding, elongating the ureters as the uterus grows, and so preventing the flow of urine; and, in a reflex way, the pressure of the uterus upon sensitive nerves and ganglia in the pelvis, and perhaps from morbid conditions in the uterus and ovaries, acting directly upon the brain, especially the medulla and pons, all the reflex centres being normally exalted in their sensitiveness during pregnancy to facilitate the ordinary processes of nutrition.

The disease is more frequent in irritable and highly sensitive organizations, and in those of corpulent habit, for, in such, excretion is not as thoroughly performed as in others. Sudden suppression of the action of the skin, too, is not an infrequent cause of the disease, causing substances of a poisonous nature to be retained in the blood which would otherwise be thrown off. Puerperal eclampsia, then, is not properly a disease, but rather a symptom of diseased conditions—particularly of the excreting organs.

With this brief description of the disease, the diagnosis is usually easy. When fully developed, the disease is not likely to be confounded with any other, except true or chronic epilepsy. The history of the case and the fact of pregnancy will easily distinguish puerperal eclampsia. Convulsions arising from disease of the nervous centres are likely to be local, affecting only the portions of the body supplied by these centres. Diseases of the meninges of the brain or spinal cord, producing convulsions, are likely to be attended with pain, fever, and irregular nervous disturbances, which readily point to the location of the disease. The determination of whether the eclampsia is due to acute or chronic disease of the kidneys is of little moment in diagnosis, but is of great importance in the prognosis of the case.

The most important diagnostic symptoms for the physician to note and rightly interpret, are the various nervous disturbances, such as severe headache, dizziness, persistent nausea and vomiting, diarrhœa coming on suddenly and watery in character, insomnia, special senses disordered—as dimness of vision, spots floating before the eyes, ringing in the ears, disagreeable taste and smell—disturbance of motor nerves, irregular spasms of voluntary and involuntary muscles, reflexes unusually active.

Œdema, general or local, temporary or continuing, should always attract attention to the condition of the excretions, and examinations of the urine be made regularly and frequently. Defective excretion by the bowels and skin should likewise be noticed and corrected.

Poisoning by lead, arsenic, or the preparations of mercury, is to be considered, but the history of the case is likely to eliminate these readily.

The examination of the urine is of the greatest importance to determine the presence or not of albumin and the amount of urea excreted.

The intelligent and observing physician is likely to detect readily the premonitory symptoms if he has the opportunity to look for them; but, unfortunately, he is usually first called only after the first spasm has occurred, and when the diagnosis is already made.

This is a disease, surely, in which prevention is the best cure. The prognosis is always grave, and can only be fully determined when the extent of the lesions in vital organs is known, and the rapidity with which the excreting organs are carrying off the poisonous substances. The more frequent the convulsions the longer they continue, and the greater their severity the more serious is the prognosis. The continuance, after delivery, of serious organic disease of the kidneys and lesion of important structures in the brain as the result of the convulsions, will complicate the ultimate recovery and render the prognosis uncertain. The diminishing frequency and severity of the spasms, with the free secretion of urine, with urea increasing and albumin decreasing, and a subsidence of the nervous disturbances, will enable us to hope for a speedy and complete recovery and no return in subsequent pregnancies.

DR. EDMUND J. DOERING then spoke on the

PROPHYLAXIS OF PUERPERAL ECLAMPSIA.

Albuminuria during pregnancy may not cause puerperal eclampsia, and eclampsia may occur without a renal lesion, but the fact remains that the danger of puerperal eclampsia is manifoldly increased when a pregnant woman suffers from renal insufficiency, whether the same be organic in character or due to mechanical interference with the renal circulation. It is our duty then to examine carefully from time to time the urine of every pregnant woman. It is unfortunately true that in the majority of cases of pregnancy the urine is never examined. It is also true that in the majority of cases in which the urine is examined, the heat or nitric acid tests constitute the so-called "urinary analysis." The fact seems to be utterly ignored that the urine may be and often is entirely free from albumin and still indicates the existence of a serious renal lesion. We have not done our duty to our patient, particularly if she be a primipara, till we have determined the exact amount of urine secreted in twenty-four hours, and ascertained the actual specific gravity, so as to know the amount of solids passed, together with a careful chemical and microscopical analysis of a mixed sample. Occasional faint traces of albumin occur in a large percentage of pregnant women, and is of no special significance provided the quantity and specific gravity of the urine remain normal. But the persistence of albumin or the presence of casts with or without albumin, or a diminished amount of solids passed in twenty-four hours, indicates the necessity of prompt prophylactic treatment to ward off eclampsia.

The patient should be clad in woollen garments. Extra precautions should be taken to prevent chilling of the body by exposure to cold or wet. The diet should consist principally, if not entirely, of milk, which can be consumed in quantity varying from two to four quarts per diem. Fruit and fish may be permitted, also farinaceous articles of food and some vegetables. Meats are to be used sparingly, if at all; moderate exercise may be advised. The therapeutic indications are, of course, to keep up a free action of the skin, bowels, and kidneys. Warm baths should be regularly employed. The bowels should be moved daily, and an excellent laxative for this purpose is cream of tartar in tablepoonful doses every morning. Compound jalap powder has also a favorable action. In anæmic subjects iron in the form of Basham's mixture given several times daily will be of decided benefit, being tonic, diuretic, and diaphoretic in its action. Infusion of digitalis, in combination with acetate, citrate, or bitartrate of potassium, is also an excellent remedy. The patient should be advised to partake freely of fluids, and Vichy, Buffalo Lithia, and Londonderry Lithia waters are specially indicated. If there is great nervous irritability, rectal injections of chloral at night will be of great service. Finally, if we have exhausted all these measures and the symptoms become worse, the dropsy increases, or the central nervous system becomes involved, the induction of premature labor may have to be seriously considered or become absolutely necessary.

DR. CHARLES WARRINGTON EARLE then spoke on

THE TREATMENT OF PUERPERAL ECLAMPSIA.

Notwithstanding everything which has been suggested in the way of prevention and treatment during the past twenty years, puerperal eclampsia still remains the *bête noir* of obstetrics.

According to many of the older teachers, one-half of the patients attacked with the disease died; and in all the cases which Fordyce Barker could collect up to 1855, thirty-two per cent. occurring before and during labor, and twenty-two per cent. of those after delivery, ended fatally. In this gentleman's practice to 1874, the mortality had diminished to fourteen per cent. Any treatment decided upon must necessarily be varied according as the treatment is administered to one early in pregnancy, during parturition, or after delivery.

The means for treating this terrible condition may be ranged under the following headings:

Evacuants and Detergents.
Nerve Sedatives and Anodynes.
Anæsthetics.
Bleeding.
Operative Measures.

The remedy indicated, or the procedure which offers the best result, differs according to the time of the eclamptic attack. The treatment, then, whatever it is to be, should be considered during the following periods:

Before, during, and following labor.

Whatever the time may be, however, or what plan of treatment it is proposed to inaugurate, it goes without saying that nothing of an exciting nature which can be avoided should be used; that the surroundings should be such that good air and freedom from incumbrances as regards clothing, etc., are insured. If vaginal examinations are objectionable to her, no more than simply enough to acquaint ourselves with the absolute progress of the dilatation of the os should be made. Indeed, every cause which may produce worry on the part of our patient must be avoided.

We must remember that, however well demonstrated the uræmic theory may be to us, there have been during all times a goodly number who believe that puerperal eclampsia is a neurosis, and that any reflex irritation of the spinal system is liable to exaggerate the convulsions.

TREATMENT DURING EARLY PREGNANCY.

Sometimes the attack has been expected; for while exceptionally it takes place without any premonitory symptoms, usually there is œdema, or a terrible neuralgia, or a condition of the nervous system that has caused the experienced accoucheur to expect it. The patient has had preventive treatment. It does not suffice; the convulsion is on. We must now shape our treatment for this case with the knowledge that a single convulsion may cause the death of a patient, and that it is the rule that usually in two days either a cure is effected or a serious complication makes its appearance which will prove fatal.

As rapidly as possible these things should be done: A little chloroform given; the patient put in a hot bath; and a non-irritating cathartic—one which will produce a large, watery stool—administered. Whatever procedure may be adopted later in the case, it appears to me that the foregoing treatment is plain. Of course, as adjuvants, a hypodermatic of morphia may be given and a dose of chloral, either by mouth or rectum. The question will also arise at once as regards the expediency of using pilocarpine as an aid in the elimination by the

skin of retained excrementitious matters. The value of this remedy will be discussed later.

More than a passing notice should be given to the hot baths. They are extensively used in many of the largest obstetrical hospitals. "The patient is placed in a bath-tub filled with water at a temperature slightly above 99° F. The tub is then covered with a heavy blanket, leaving the face free, and the temperature is gradually elevated to 110° or 112° F. She remains in the bath thirty minutes. A towel wrung out of ice-water and placed upon the head relieves any distressing cephalic sensations. While in the bath the patient drinks large quantities of water. Upon emerging from the bath she is covered with a warm sheet and enveloped in an upper and lower layer of thick blankets, so that only the face is exposed. Within a very few minutes free perspiration is observed. The sweating is continued for two or three hours. According to the gravity of the case, the hot-water bath may be repeated once daily for an indefinite period. The relief of all threatening symptoms under this simple plan of treatment alone is surprising. Sometimes the hot-water bath acts as an efficient excitant of uterine contractions, and premature labor is induced."

Concerning the usefulness of chloroform and chloral, there is no doubt. The administration of both have their opponents, but in the speaker's judgment they are exceedingly useful.

Some of the most brilliant recoveries in the literature have come about from hypodermatics of morphia, rectal administration of chloral, aud the inhalation of chloroform. He should not fail to suggest, even in a case where the convulsions are occurring thus early in pregnancy, the propriety of venesection.

If the convulsion persist for a long time or if the attacks come frequently, the question of the induction of labor would suggest itself even thus early. This, however, is a subject concerning which authorities do not by any means agree. The question comes fairly before us early in pregnancy, or any time before labor commences with the os not dilated. Are we justified in attempting an operation the irritation of which may possibly produce a convulsion, and the completion of which may not cause a suspension of the attack for which the operation is commenced?

The speaker ranged himself with those who would consider the propriety and justifiableness of carefully—while meeting all therapeutic indications—evacuating the uterus of its contents.

TREATMENT OF ECLAMPSIA DURING LABOR.

Some of the factors entering into the treatment of convulsions during pregnancy or before full term and which are not fully agreed upon by the profession, do not engage our attention at this time; for instance, the induction of labor, either in the interest of the mother or child. Labor has already commenced; the convulsion is present. To him there is no question as to the propriety of hastening it (labor) by every means possible, and the possibility of producing a convulsion by artificially dilating the cervix is so small that it need not be entertained.

In a considerable number of cases which he had collected from the journals published during the last two or three years, and which do not enter into any of the tables published in the text-books, there are some data favoring venesection at the time. Indeed, Swayne says that in thirty-four cases occurring in his practice bleeding, anæsthetics, and delivery—in the order named—have given the best results. James Murphy (*Lancet*, 1886), however, in the treatment of five cases with pilocarpine as the principal remedy, aided by other adjuvants, has saved all his patients. His plan is to inject subcutaneously from one-fourth to one-third grain of this drug every six hours, and his results are certainly remarkable. In one of his cases thirty-three convulsions occurred during the seventh month, but after the use of the pilocarpine premature labor was averted and a healthy child born at term.

Returning, however, to consider bleeding, it should be said, according to Kucher, that this procedure has been entirely abandoned in the Vienna clinic, and the same author says it is very doubtful whether it ever has any beneficial effect whatever. In fifty-two cases, upon which he bases his paper, only seven were fatal. This is an excellent showing when we consider that the mortality was formerly twenty to thirty per cent. They depend in the Vienna hospitals upon diuretics, diaphoretics, and cathartics. It is also believed that the indication is to expedite labor by all reasonable means, but that too active interference is more dangerous than the eclampsia.

The use of veratrum viride, since the days of Fordyce Barker, has had its advocates, and more recently, in a discussion which took place at the Ninth International Medical Congress, it found a considerable number of advocates. Dr. Jewett, of Brooklyn, in an experience of twenty-six cases, seems to show that in veratrum viride, if given early, we have a well-nigh certain means to prevent death from puerperal eclampsia. Some one has said if the pulse be kept at 60 by veratrum no convulsion can take place. Dr. Jewett gives the drug hypodermatically, and keeps the patient quiet and in the lying position.

Breus has had remarkable results from the hot pack—seventeen cases and only two deaths. It is claimed for this treatment that it does not induce abortion or premature labor. Patients are immersed in the hot bath, and its action continued by the hot pack in blankets. In many cases the results are not as good as they might be, from the fact that the details of treatment are not fully and faithfully carried out.

If chloroform is used it should be continuous and its effect profound. If chloral is to be used, and cannot be given by mouth, thirty or forty grains should be given by rectum, and repeated in twenty minutes, if necessary.

With the present light on the subject, it appears that for convulsions at full term the hot bath, anæsthetics, and a termination of labor as rapidly as can be done without injury to the soft parts, is the treatment for to-day

FOR CONVULSIONS AFTER DELIVERY.

Here factors are wanting which were present while the woman was in labor. The uterus has been emptied of its contents, but the convulsions continue. The induction of labor or rapid delivery by version or forceps cannot now be considered. The indications are to control the eclamptic attack with an anæsthetic, and to eliminate with all rapidity by the skin, bowels, and kidneys. In addition to the hot bath, we now have the pilocarpine, aided by what seems to be the best cathartic—elaterium. To produce the full effect of the last-named drug, we should have at our command as potent a hypodermatic

tablet as we have of pilocarpine or morphia. This is particularly true for cases which cannot swallow.

To sum up, then, we have:

1. For convulsions before delivery: The hot bath, morphia and pilocarpine hypodermatically, chloral and bromide of potassium by mouth or rectum; veratrum viride to reduce heart's action and lower arterial tension; possibly bleeding; the induction of labor.

2. For convulsions during labor: The hot bath, morphia, chloral, anæsthetics; a rapid delivery with all precautions.

3. For convulsions after labor: Control eclampsia by anæsthetics, and rapid elimination by all the emunctories.

(To be concluded.)

NEW YORK ACADEMY OF MEDICINE.

SECTION ON ORTHOPÆDIC SURGERY.

Stated Meeting, April 19, 1889.

A. B. JUDSON, M.D., CHAIRMAN.

DR. V. P. GIBNEY presented a patient, a girl fourteen years old, on whom he had operated for

DOUBLE PSOAS ABSCESS FOLLOWING POTT'S DISEASE

of nine years' duration. The carious vertebræ were evidently consolidated, when last November abscesses were discovered, and the patient was brought under treatment. On the right side the tumor was incised in Scarpa's space, and long forceps were passed under Poupart's ligament through the iliac fossa and into the lumbar region, and a counter-opening was made on the forceps along the border of the erector spinæ muscle. Pieces of bone escaped with the pus. The cavity was curetted and the bone scraped gently. With antiseptic dressing and injections of carbolic acid solution 1:40, and one per cent. creolin solution, both wounds closed in a month. The left side was then operated on by simple incision and drainage. Large quantities of bone detritus were scooped out with the finger. A sinus still remains on the left side from which a piece of bone is occasionally discharged.

The case was exhibited as showing the advantage of Owen's method over attacking simply the sac and not the whole suppurating track.

Dr. Gibney believed it would have been better to treat both sides according to Owen's method; but in general he doubted the propriety of doing this operation during exfoliation, which would necessitate a subsequent operation. It is also important that the patient should be in a pretty good condition.

DR. R. H. SAYRE had used injections of peroxide of hydrogen in large abscess cavities, with better results than from carbolic, or bichloride, or boro-salicylic solutions.

DR. GIBNEY said that a similar experience had been reported by Dr. Vance.

DR. JUDSON thought an objection to operating on these cases was that for the natural incarceration of the pus and detritus we substituted an artificial opening, necessitating antisepsis to hasten cicatrization. If these accumulations are doing no harm, it is better to leave them for removal by natural processes; and if in due time they perforate the skin, the general and local conditions are ready to promote evacuation and speedy cicatrization.

DR. J. A. WYETH said that the operation is indicated when large abscesses are situated on exposed parts of the body, and liable to injury and subsequent septic complications. He recalled the case of a woman who, thirteen years after being cured of Pott's disease, slipped and fell on a large gluteal abscess. The accident speedily gave rise to symptoms of sepsis, with high febrile movements, and several operations under ether were necessary for the removal of bone detritus, which was spread through the gluteal muscles. The patient ran great risks, but finally recovered. He had had other similar cases. A psoas abscess behind the peritoneum causing no trouble should be left alone, but one pointing in the thigh, back, or other exposed situation should be operated upon. as the danger of the operation is almost *nil*.

DR. N. M. SHAFFER was reminded of the history of a patient with Pott's disease and an abscess occupying the gluteal region and the anterior part of the thigh. The child fell, striking the gluteal tumor. The immediate symptoms were alarming, but without the adoption of any special treatment, the accident resulted in the entire disappearance of the abscess. If there were any means of determining with certainty when an abscess from Pott's disease contains bony detritus, it would be preferable to operate; but while spondylitis is still active, it is better to postpone operation as long as possible. He recalled a case of Pott's disease and hip-joint disease which he had been watching for several years, where spiculæ of bone as large as the end of the finger were expelled in a sudden and violent attack of coughing. The bone was undoubtedly from the cancellous structure of the sixth or seventh cervical vertebra. The patient was relieved at once, and physical examination showed that very little trouble had been caused by the entrance of the bone through the lung-tissue into the bronchial tubes.

KNOCK-KNEE—CLUBFOOT—DEFORMITY FOLLOWING HIP-DISEASE.

DR. WYETH related two cases in which he had corrected in- and out-knee in the same patient by double osteotomies. The patients were three and a half and four years old respectively. Both were discharged entirely relieved. Strict antisepsis was followed and the limbs were dressed in plaster-of-Paris in a position of over-correction. He prefers MacCormac's incision on the outer side and just above the capsule, since the saphena vein and anastomatica magna artery are not endangered, as in Macewen's operation on the inner aspect of the thigh. He also briefly related three cases in which patients, aged thirteen, eighteen, and twenty-six years respectively, had been relieved of the deformity following hip-disease, and restored to good locomotion by operations on the femur. The method pursued was Gant's osteotomy below the lesser trochanter. The after-treatment had been Buck's extension and Hamilton's long splint. In one of the patients there had been double hip disease. Two months after the left femur had been operated on the right was operated on; and four months after the date of the first operation the patient was discharged cured, with good locomotion.

He also related two cases in which congenital talipes equino-varus of the most exaggerated type had been corrected with good recovery, and with the feet in excellent shape. Tenotomy of the tendo-Achillis, tibialis anticus,

and tibialis posticus was first done; the first two subcutaneously, and the last by open incision, the tendon being dissociated from that of the flexor digitorum, and divided on an aneurism needle. The operation was completed by an osteotomy as follows: An incision was made on the outer side of the dorsum, exactly over the point of greatest convexity; the tissues were lifted from the tarsus by an elevator, and a conical section including portions of the calcaneous, astragalus, cuboid, and scaphoid was removed. The rule should be to remove all parts which prevent replacement of the foot. The foot being brought into normal position by eversion and rotation, aseptic dressing and plaster-of-Paris completed the treatment, the result of which was excellent.

DR. GIBNEY said that the anatomical point raised in the paper concerning supra-condyloid osteotomies certainly commends to us the operation of MacCormac. Although in- and out-knee in the same subject is rare, he had seen many instances of multiple deformity among Bohemians and Italians. He had recently done a sextuple osteotomy at one sitting, and is treating an ununited fracture of the right tibia, all the others having united.

DR. JUDSON thought that in congenital talipes the reduction of the deformity by mechanical or operative means is easy; but that is a small part of the necessary treatment. So long as the patient is growing, he must be under occasional observation, and, if necessary, made to wear for a few months, at intervals of two or three years, a brace fitted to the present needs, in order to prevent threatened relapses. In the deformities of the knee, there is especial reason for preferring mechanical means of correction, because here we have the advantage of the leverage found in the tibia and femur; while in clubfoot, there is only the tibia on one side, and, on the other, the short and many-jointed foot.

DR. H. L. TAYLOR said that late observation of the results of treatment is of especial importance in orthopædic practice. If surgeons and orthopædists would report the condition of patients five, ten, or more years after dismissal, a more intelligent choice of methods could be made.

DR. SHAFFER said that his experience with mechanical appliances in the treatment of talipes, leads him to think that many severe operations are performed on patients who could be better treated by traction. He recalled a case in which there was confirmed equino-varus, although three or four tenotomies, and five or six osteotomies had been performed. He had applied the "external lateral stretcher" and the patient is now walking on the flat of the foot. He referred to the interesting question whether osteotomy is advisable when there is motion in the hip-joint. In a patient on whom Dr. W. T. Bull had operated, some motion was found after etherization. The reduction of the deformity by osteotomy had been followed by persistent traction with the hip-splint; and good position and slight motion had both been retained.

DR. GIBNEY believed that the presence of motion is not a contra-indication to the operation. About six months ago, he had performed Gant's operation for a right-angled deformity. The flexion had been reduced from 90 degrees to 15 degrees, and the limb was retained at 15 degrees of flexion by a traction apparatus for three or four months, when it was removed and the patient allowed to walk about with a high shoe. After about six weeks, the flexion had increased to 25 or 30 degrees. Traction was re-applied, and the limb is being again brought down. He recognized the necessity of protective apparatus in order to retain or increase the result secured by operation.

DR. WYETH had operated in several cases where there was motion, and had refused to do it in others. In a patient whom he had seen with Dr. L. A. Sayre, there was considerable motion, and he had done a tenotomy for temporary relief, postponing osteotomy.

DR. R. H. SAYRE said that in the case referred to, improvement had followed the tenotomy, but an apparatus is necessary to prevent a return of deformity. He thought that in some cases sufficient reduction of the flexion might be brought about by section of the psoas and iliacus muscles. This had been done in one case in which, although the operation had been subcutaneous, injury of the vessels had been avoided. By open section, this danger would be avoided.

DR. J. D. WILSON expressed surprise at the frequent mention of elevations of temperature in the history of Dr. Wyeth's cases, which had been treated antiseptically. Have our teachings been too absolute, or do such temperatures really indicate imperfect antisepsis?

DR. WYETH replied that "the temperature of reaction," occasionally as high as 102 degrees, occurred in the first twenty-four hours, but it usually fell to normal in forty-eight hours. Traumatism, ether, shock, and the use of sublimate combine to produce this reaction, which might still be called an aseptic temperature. He closed the discussion by saying that the simplicity and safety of osteotomy had been shown by the cases he had reported. While no case of equino-varus treated the first two years of life should require tarsotomy, neglected cases will present themselves where nothing but tarsotomy will give relief. The operation may give considerable foreshortening to the foot, but one can certainly correct the deformity, however great, by removing enough bone; and if this be properly done, he believed it to be real conservatism.

CORRESPONDENCE.

THE INTERNATIONAL CONGRESS OF ALCOHOLISM.

THE International Congress of Alcoholism held its meeting in Paris from July 29th to August 1st, under the presidency of Dr. Dujardin-Beaumetz.

Three questions were to be treated principally during the session, the first being on the "Relations existing between the increase of the use of alcohol and the increase of insanity and criminality."

One of the important points in answer to this question was to learn the comparative increase of drinking saloons in different countries. M. Ivernés, Chief of Statistics at the French Ministry of Justice, was charged with the study of this question. Statistics very plainly show that there is an increase of crime in direct proportion to the increase of alcohol taken by each inhabitant. In France from 1873 to 1877, the average annual quantity of alcohol taken by each inhabitant was 2.72 quarts; from 1878 to 1882, 3.53 quarts; from 1883 to 1887, 3.83 quarts. During this time, the number of crimes and offences increased from 172,000 to 195,000, and the

number of insane people from 37,000 in 1872 to 52,000 in 1885.

In Belgium, from 1868 to 1882, each inhabitant on an average took from 7 to 9 quarts of alcohol; the number of crimes and offences increased from 1868 to 1882 from 1900 for every 100,000 inhabitants to 2877. The number of insane, which was 8.240 in 1868, has gone up to 10.020 in 1878.

In Italy, from 1872 to 1885, the quantity of alcohol taken increased from 2.7 quarts to 5 quarts for each inhabitant. From 1879 to 1885 the number of criminals increases from 1400 to 1500; the number of insane from 15,000 to 22,000.

These facts clearly show that there is a direct increase of crime and insanity with the increase in the use of alcohol; on the other hand, an additional proof is the fact that a decrease of the use of alcohol in a country is accompanied by a corresponding decrease in the number of crimes and insanity. In Norway, as was stated by M. Cauderlier, in 1844, each inhabitant on an average took 10 quarts of alcohol; in 1871, only 5 quarts; in 1876, 4 quarts. During this same time, the criminal statistics came down from 249 per 100,000 inhabitants to 207 and 180; while the number of insane patients came down in the same proportion.

The next question was "How to do away with this increase in the use of alcohol?" Dr. Drysdale, of London, recommended the suppression of the use of alcoholic liquors, as he mentioned the fact that life insurance companies find that those who abstain from the use of alcohol live about six years longer than others. This proposition, if it could be accepted, would be a very good one, but it is impracticable, especially in countries where they make wines. This being impracticable, the next proposition to take into consideration is whether it would not be possible to diminish the number of drinking places; but here the members of the Congress became quite divided, some averring that no good can be derived from such a measure, while others sustained it.

M. Cauderlier mentioned the fact that in Holland a law was passed to restrict to a maximum number the drinking places of each city; yet although this law has been strictly carried out, the number of crimes and insanity has not diminished in Holland; which is explainable by the fact that the same quantity of alcohol having been used, it probably was taken by the individuals in their own houses.

M. Milliet, of Switzerland, mentioned the fact that in the district of Thurgovia, where there are a great many drinking places, there are very few alcoholic persons; while in the district of Berne, where very few drinking places can be found, the number of alcoholics is very great.

M. Vaucleroy, of Belgium, said that we know that the quantity of alcohol employed has a tendency to increase every year; while in Holland, where the number of drinking places has been reduced, the quantity of alcohol used has remained the same, it is true, but has not increased, which demonstrates that the promulgation of the law has been of some utility.

Finally, the Congress voted on the two following propositions:

1st. "The increase of the use of alcohol is one of the principal causes of criminality, suicides, and insanity."

This proposition was unanimously adopted.

2d. "The diminution of the number of drinking places being one of the causes of the reduction of the use of alcohol, the Congress invites the government to take the necessary measures to reduce the number of drinking saloons."

This proposition was unanimously accepted, except by M. Milliet, who protested against it.

The second question placed before the Congress was, "The legal means to prevent the accidents, crimes, etc., due to insanity."

M. Motet opened the discussion by drawing attention to the fact that French laws contain no paragraph in regard to the responsibility of an alcoholic who commits a crime; the criminal is condemned more or less seriously according to the circumstances presented, but there is no strict article in regard to it. In civil law, on many occasions, a contract which had been made by a man in an alcoholic state has been declared null; the alcoholic state in such cases has been compared to insanity.

There are three different types of alcoholics: 1st. Simple non-pathological alcoholism. 2d. Pathological alcoholism with cerebral lesions. 3d. Pathological alcoholism with incurable cerebral lesions.

In the first category are placed simple or accidental alcoholism, to which belong the ordinary drinking persons, who, although not drunk, are under the toxic influence of alcohol.

The second division comprises all the pathological forms of alcoholism on the one hand, and all the subacute, acute or chronic mental states which are due to alcoholic intoxication.

In this class are placed all the insane, the degenerated, the epileptics, who are liable, when under the influence of alcohol, to be led to extreme and dangerous acts, which they would never do if not under this toxic influence.

M. Motet thinks that drunkenness is to be punished, as well as the crimes or offences committed while under its influence, when it is simple drunkenness, which could have been prevented by the patient himself. Drunkenness is also punishable when it is proven that alcoholic excitation has been produced for the purpose of committing a crime. There are also punishable, but to a less degree, those whose inferior intellect diminishes their tolerance toward alcoholic liquors on account of their inferior cerebral organization. Again, crimes or offences are not punishable when they have been committed while the individual is in an acute or subacute state of delirium tremens; the same can be applied in chronic alcoholism, where definite cerebral lesions exist; in such cases the patient is to be placed in an asylum until he presents no more alarming symptoms.

M. Decroix did not think it right to consider an alcoholic crime as an irresponsible one, nor does he believe that after one has committed a crime while under the influence of alcoholism, and has been placed in an asylum, that he ought to be allowed to run about after his apparent cure.

M. Duverger examined how the habitual drunkard is treated in other countries. He cited the English law promulgated in 1879, which says that an "habitual drunkard is an individual who cannot be considered as a true insane person, but yet who by his habits of drinking excessively alcoholic liquors is dangerous at certain moments for himself as well as for his sur-

roundings, and is then incapable to direct his person or his business. The habitual drunkard has also a right to ask his admission into a special asylum, but under only very few conditions can he be allowed to leave the asylum before the date which he himself mentioned in his demand."

In Georgia, the State possesses, at Midway, a public asylum for insane, in which are admitted the insane, idiots, epileptics and drunkards who have become insane —a certificate signed by three honorable physicians being necessary to allow the admission of the patient.

In France, although there is a law authorizing the confinement of any alcoholic insane, yet it is very rarely done, and their admission is often a matter of difficulty; this same law also mentions the fact, that any alcoholic who had been confined could be allowed to leave the asylum by a written certificate of all the physicians of the hospital.

The French Society of Temperance has asked that the Minister of Justice should be able to pronounce the interdiction of a person, who, by alcoholic habits, is found oftentimes in an habitual state of insanity, even if that person is married or has parents around him. Again, as the state of chronic alcoholism is not an absolute loss, but only a diminution of responsibility, the Minister of Justice could be allowed to nominate a judiciary counsel, which would be a semi-interdiction. Then if the interdiction or semi-interdiction is pronounced for insanity or feeble-mindedness due to the abuse of alcoholic liquors, the tribunal could be allowed to decide that the said person should be placed in a special asylum.

At the Congress which took place in Bruxelles, some time ago, a proposition of this kind was voted, that "all recognized alcoholics should be placed in interdiction on the demand of their family and the supreme judge of the district, and placed for a determined time in a special asylum."

M. Duverger says, that the fear of being interdicted or semi-interdicted for all business affairs on account of the abuse of alcohol would certainly act as a preventive against alcoholism; and the same fear would also exist as being locked up in a special asylum as an insane patient. In addition, the confinement of alcoholics, as insane or semi-insane, which would prevent them from committing any crime, would contribute to prevent one of the greatest misfortunes which can happen to a society, the condemnation of an irresponsible person.

M. Fournier de Plant approved the interdiction and judiciary counsel as an excellent remedy against alcoholism; he cited the fact of his having beeen on the judiciary counsel of a young and rich alcoholic, who was completely cured of the habit of drinking, on account of the difficulties which this counsel brought in preventing the young man from satisfying his habit.

M. Gouse then, opening another subject, said that it would be wise to recommend the creation of a certain number of drinking places, in the neighborhood of large manufactures, in which only non-alcoholic liquors could be found. These places ought, of course, to be under the direction of a society, which would have no interest in the business; these places could be very cheaply built and would be of very little expense to the temperance societies.

M. Bardy next spoke on the methods of recognizing the falsification of alcoholic liquors, and said that any alcohol containing more than 2 parts in 1000 of impure material ought to be excluded from circulation and ought not to be used.

The Congress then adjourned.

PARIS, August 8, 1889.

THE MORTALITY OF PNEUMONIA IN MALARIAL AND NON-MALARIAL DISTRICTS.

To the Editor of THE MEDICAL NEWS,

SIR: In the admirable paper on the mortality of acute lobar pneumonia, which appeared in the issue of THE MEDICAL NEWS, July 27th, one point of very great interest, as it seems to me, was overlooked, nor has it been considered in any of the other papers on the subject which have appeared from time to time in the medical journals. It is the mortality from this disease in malarial and non-malarial districts respectively. I do not refer to the complication with intermittent or remittent fever. Drs. Townshend and Coolidge refer to the influence of the former of these diseases in their paper, but I refer to the death-rate from pneumonia in malarial and non-malarial districts irrespective of any *apparent* complications with malarial disease in the former.

Conversation with physicians living in malarial regions has satisfied me that the mortality from pneumonia is far greater there than in sections of country where malarial affections do not prevail. My own practice has been for the most part in a section of country where malaria is practically unknown, so that I have been unable to make any comparison myself. I write, therefore, with the hope that such a comparison may be instituted by those in a position to investigate this point.

Possibly a study showing the prevalence of malarial affections and the death-rate of pneumonia at different times in the population supplying some of our large city hospitals with patients would throw light on this important subject.

In Piedmont, Virginia, where malaria does not prevail, pneumonia is considered one of the least dangerous of the acute febrile diseases, and it is rare to hear of a death from this disease, except in the aged or in those who have been habitually intemperate. On the other hand, I am told by physicians living in malarial sections of the State that pneumonia is one of the most fatal diseases with which they have to deal.

It will be time enough to consider the causes of the increased mortality of this disease in malarial districts when the fact of such increased mortality has been definitely established.

I trust that the subject will soon be investigated, and some positive conclusions reached.

Yours truly,

WM. C. DABNEY, M.D.

UNIVERSITY OF VIRGINIA,
August 21, 1889.

THE DIETETIC TREATMENT OF CHRONIC BRIGHT'S DISEASE.

To the Editor of THE MEDICAL NEWS,

SIR: I have read with unusual interest your review of the experiments and conclusions on that very important and interesting subject, "The Dietetic Treatment of Chronic Bright's Disease," by Semmola, Senator, Schreiber, etc. I have been giving some special attention

to this subject in cases recently under treatment by myself. In two cases of chronic diffuse nephritis, I have made milk and raw eggs the principal articles of diet, with the use of tr. ferri. chlor. and trinitrin, alternated with digitalis, with a gradual but steady diminution of albumin. One patient is aged sixty, and quite anæmic. The diet is undoubtedly the most important feature in the treatment in most of these cases.

I hope you will pardon me, but I cannot help adding my mite to a question of so much vital importance to humanity generally, and one upon which there have been so many conflicting opinions expressed and such diversity of views in discussion.

I am, yours very respectfully,

J. R. VINCENT.

WILKINSBURG, PA., Sept. 3, 1889.

NEWS ITEMS.

Statistics from Pasteur's Institute.—The latest returns from Pasteur's Institute, quoted from the *Union Médical*, August 24th, are as follows:

During the month of June of this year, 169 patients were treated at the institute. These comprised 24 who were bitten by animals which were experimentally proven to be suffering from rabies; 115 who were bitten by animals which were reported as mad after veterinary examination; 30 who were bitten by animals suspected of rabies.

The animals in question included 143 dogs, 24 cats, 1 horse, and 1 ass.

One case, which was brought under treatment seventeen days after having been bitten, and who was treated for two weeks, died of hydrophobia ten days later. Another case, which was admitted to the institute almost immediately after being bitten, and who was treated for six days, was seized with rabies nine days later.

Cheap Medical Service.—We read in the *Medical Record* for August 31st, that an association has been formed in New York which advertizes to furnish medical attendance to its subscribers for forty cents a month, and that all prescriptions for its subscribers will be filled by the leading pharmacists of that city for twenty cents each. "In all probability," says the *Record*, "the services and the medicines are not worth even that."

Austrian Pharmacopœia.—We read in the *Wiener klin. Wochenschrift* of July 11th, that the seventh edition of the Austrian *Pharmacopœia* has just been published. From January, 1890, all drugs and preparations must be dispensed according to the new *Pharmacopœia*; the druggist is also compelled to keep in stock a list of surgical supplies, including catgut, bandages, antiseptic gauzes and cotton, protective, drainage tubes, and the like. The new edition will contain a very large number of new drugs.

Fraud in Life Insurance.—A medical man of Belfast, Ireland, has been brought into court on a charge of fraud in regard to an examination for life insurance. He was found guilty of having declared as sound and healthy a person who had cardiac disease, with dropsy, and who died soon after. He was sentenced to imprisonment for six months.

Health in the French Army.—According to the official report of the French Minister of War, the mortality among the French troops has fallen from twelve to eight per thousand during the last year. From 1875 to 1887 there have occurred 141,648 cases of typhoid fever, and 21,116 deaths. The percentage of this disease has materially decreased of late, owing to the attention that is being paid to pure water supply in the barracks. The value of vaccination is proved by the fact that the number of smallpox cases has fallen from 1042 to 242, and these were mostly among recruits.

A Dog without a Brain.—At the last meeting of German neurologists, held in Baden-Baden, Prof. Goltz, of Strassburg, reported a most remarkable experiment. He cut out, in two operations, almost the entire cerebrum of a dog, leaving only the cerebellum and a small portion of the base of the cerebrum. The animal lived for fifty-one days after the last operation, and then died of pneumonia. The remarkable part of the experiment was the influence it had on the dog, who, a few hours after the operation, raised himself on his hind legs, put his paws over the side of his box, and looked inquiringly around. He could walk, eat and drink, and would chew any food that was placed in his mouth. Waking and sleeping alternated naturally. He was restless before feeding, but afterward would become quiet and sleep. A slight touch would awaken him from sleep. During urination and defecation the animal assumed the normal position. Hearing, taste, and smell were, of course, absent.—*Wiener med. Presse*, July 28th.

London Hospitals.—According to the *New York Times*, London has 81 hospitals and 50 dispensaries which are supported by voluntary contributions. These hospitals contain 8012 beds, of which number 5926 were occupied every day of last year, the number of patients being 74,316. Besides these, 1,038,427 out-patients were treated at the dispensaries and out-service departments of the hospitals. How many recurrent cases are included in these aggregates it is not possible to discover, but the reports do not suggest that there are any, so that if the statements are absolutely correct, they show that fully one in every four of the inhabitants of London receives gratuitous medical treatment when ill, a condition which at least suggests large abuse of this form of charity and want of vigilance in its administration.

New Method of Precipitating Sewage.—The problem of the disposal of the sewage of large towns has long defied the efforts of sanitary engineers to cope with it in a satisfactory manner. A new method of sterilizing and precipitating sewage has just been brought out which, it is claimed, accomplishes all that can be required of it at as little cost as any such system can be worked. The method has been put in practice experimentally at the Wimbledon sewage works, England. The principle underlying this plan of dealing with sewage is the employment of "amine" salts, in combination with milk of lime. At Wimbledon herring brine is used, and on mixing with the lime a very soluble gaseous reagent is evolved, to which the inventor has given the name of "Amerinol." This reagent possesses a peculiar briny odor, and when introduced into sewage is said rapidly to extirpate all microörganisms capable of causing putre-

faction or disease. The effect is almost instantaneous. By the action of the lime violent flocculation is caused, and subsidence takes place in about half an hour, the putrid smell of the sewage being replaced by the peculiar briny odor. According to Dr. Klein, the destruction of microörganisms is absolute. The total cost per annum of treating London sewage by this method is put at £125,000. Should the residue prove to possess any value for agricultural purposes its sale would tend still further to reduce the expense.—*Medical Press and Circular*, August 31, 1889.

Vaccination in Japan.—Vaccination has been obligatory for some years in Japan, and every infant is required by the police to be vaccinated. The value of the procedure is, however, well recognized by the people themselves, and the government hospitals in every town are always thronged with applicants on the weekly "vaccination day." In 1886 there were 1531 vaccinations to each 10,000 inhabitants.

Female Physicians in England.—There are at present 73 female physicians in England holding diplomas and licenses to practise. London possesses 22, other cities 34, and 17 in India are also included. The new Hospital for Women has a staff composed entirely of "lady doctors," although the consulting physicians are of the sterner sex. The medical school for women has a faculty of 48 professors, 4 of whom are ladies, and 91 students.

Typhoid Fever at Basle.—An epidemic of typhoid fever has been raging at Basle since the beginning of June. There have been so far 450 cases, with 31 deaths. The water-supply has been tested chemically and bacteriologically without anything being found to account for the outbreak. The epidemic is now subsiding.

The Death of Professor Loreta.—This eminent man, who was recognized as the leading operator in Italy and one of the foremost practical surgeons of the day, died at Bologna on July 23 by his own hand. This melancholy termination to a brilliant career has caused a most painful sensation to his professional brethren in his own country, where he was universally honored as a practitioner and both revered and beloved as a teacher. Loreta, whose hereditary title of Count was lost in the greater dignity of his professional designation, was born of a noble family at Ravenna, in 1831. Both his preliminary and his strictly medical studies were pursued at Bologna. They were interrupted for a time when he took an active part in the revolutionary movement of 1848, and it was 1858 before he took his degree. The years from 1858 to 1861 were spent in an obscure country practice; but in the latter year he was called to Bologna as head of the anatomical laboratory, and in 1865 he succeeded Rizzoli in the chair of clinical surgery. In spite of the intense activity of his professional life, Loreta found time for politics; he was an ardent Liberal, and some months before his death had been returned to the Italian Parliament by an immense majority of his fellow-citizens. He is best known, perhaps, by his operation for the relief of stricture of the pylorus, and by his method of dilating œsophageal stenosis from below through the cardiac orifice; but his operative work covered the whole field of practical surgery. He was the first to resect the liver, and it is only a few months ago that a memorial tablet commemorating that achievement was placed in the hall of the University of Bologna. His published works include papers on a new method of perineal cystotomy, a new method of treating aneurism, remote effects of contusions of the head, and many others. Bologna honored the deceased surgeon with a public funeral.—*London Med. Recorder*, Aug. 20, 1889.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM SEPTEMBER 3 TO SEPTEMBER 9, 1889.

P. J. A. CLEARY, *Major and Surgeon.*—Is hereby granted leave of absence for two months, on surgeon's certificate of disability.—*S. O. 59, Headquarters Division of the Pacific, San Francisco, Cal.*, August 27, 1889.

With the approval of the Secretary of War, the leave of absence granted JOHN H. JANEWAY, *Major and Surgeon*, in S. O. 52, July 29, 1889, Division of the Pacific, is extended two months.—Par. 1, *S. O. 206, A. G. O.*, September 5, 1889.

By direction of the Secretary of War, a Board of Medical Officers, to consist of EDWARD P. VOLLUM, *Colonel and Surgeon;* HENRY MCELDERRY, *Major and Surgeon;* WASHINGTON MATTHEWS, *Major and Surgeon;* and JAMES C. MERRILL, *Captain and Assistant Surgeon*, is constituted, to meet in New York City, on the first day of October, 1889, or as soon thereafter as practicable, for the examination of Assistant Surgeons for promotion, and of candidates for admission into the Medical Corps of the Army. The Board will be governed in its proceedings by such instructions as it may receive from the Surgeon-General.—Par. 1, *S. O. 203, A. G. O.*, September 2, 1889.

EWING, CHARLES B., *Captain and Assistant Surgeon.*—Is granted leave of absence for twenty-one days, to commence on or about September 21, 1889, provided that at time the Post Surgeon, now on leave, has returned to duty.—Par. 5, *S. O. 201, Headquarters Division of the Atlantic, Governor's Island, New York City*, September 4, 1889.

The garrisons of Fort Laramie, Wyoming Territory; Fort Hays, Kansas, and Fort Lyon, Colorado, will be withdrawn, and the posts named will be abandoned as soon as it can be done with due regard to economy.—*G. O 69, A. G. O.*, August 31, 1889.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE TWO WEEKS ENDING SEPTEMBER 7, 1889.

NASH, F. S., *Passed Assistant Surgeon.*—Detached from the "Dale," and ordered to duty in the Bureau of Medicine and Surgery.

RUSSELL, A. C. H., *Passed Assistant Surgeon.*—Ordered to Naval Hospital, Yokohama, per steamer of September 28th.

HALL, C. H. H., *Passed Assistant Surgeon*—Detached from Naval Hospital, Yokohama, on reporting of relief, and return home.

WHITE, S. S., *Assistant Surgeon.*—Detached from Naval Hospital, New York, and ordered to the "Minnesota."

STONE, E. P., *Assistant Surgeon.*—Detached from the "Minnesota," and wait orders.

BRYANT, P. H., Detached from the "Ajax," and ordered to Naval Hospital, Norfolk, Virginia.

WENTWORTH, A. R., *Assistant Surgeon.*—Detached from Naval Hospital, Norfolk, Virginia, and wait orders.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL ARTICLES.

RECENT ADVANCES IN THE DIAGNOSIS AND TREATMENT OF SOME DISEASES OF THE STOMACH.[1]

BY L. WOLFF, M.D.,

PHYSICIAN TO THE GERMAN HOSPITAL OF PHILADELPHIA; DEMONSTRATOR OF CHEMISTRY IN THE JEFFERSON MEDICAL COLLEGE, ETC.

THE pathological conditions of the stomach have, during the last few years, received a great deal of attention and consideration by medical investigators, with the result of placing them in a new light and a more rational position.

As pathological manifestations are but abnormal physiological functions, we will have to consider the normal gastric functions before proceeding to the abnormal.

It is a well-established fact that the stomach has distinct digestive power, and it is also well known that this is due to its secretions or to part thereof. While the secretive action of the stomach, in common with all mucous membranes, results in the production of mucus, the secretion of its acid digestive fluid from the peptic glands is one peculiar to this viscus alone, and to this product the name "gastric juice" is commonly given. That portion of the acid gastric juice which has a distinct influence on its digestive properties has been definitely shown by Carl Schmidt to be hydrochloric acid. The proteid ferment, which is made active only by this acid, is known as pepsin, and the result of its action on albuminoid food as peptone.

It has of late been questioned if the hydrochloric acid secreted by the peptic glands has only the power of rendering the pepsin active, and it is held by some (G. Bunge, *Lehrbuch der physiologischen und pathologischen Chemie*) that its principal value consists in rendering aseptic the ingested food, a fact which the attempt has been made to substantiate from the result of experiments which proved that 0.3 per cent. HCl prevented septic change in meat fibre, while the average normal gastric juice contained that amount of it. Normal gastric juice undoubtedly prevents and corrects effectually septic change of albuminoid food. Felix O. Cohn, in the *Zeitschrift für physiologische Chemie*, xiv., 1, July 29, 1889, ascertains that this is not attributable to the admixture of pepsin; that even small quantities of HCl prevent the formation of acetic acid, and that lactic fermentation is prevented by as much HCl as is necessary to convert into chlorides the phosphates necessary for the development of the bacillus acidi lactici. He also states that pepsin-hydrochloric acid has the same value to prevent fermentations as that without pepsin, and that HCl united with peptones fails to inhibit or prevent fermentation, and, as is already known, to digest albuminoid food. He further confirms Ewald's observation that HCl is probably secreted at once with the ingestion of food, but is imbibed by and united with the albuminoids, also with the bases and salts it unites with or displaces, and that during this period there is nothing to prevent other fermentations.

The question of the production of HCl in the peptic glands from the alkaline blood and fluids, is one that is of interest and value to gastric physiology. That HCl must necessarily result from the decomposition of the chlorides of the blood and liquids of the body is quite apparent. As sodium chloride is the principal one of these contained in the blood and lymph, and as these also hold in solution sodium bicarbonate, it may readily be inferred how sodium carbonate can form with liberation of hydrochloric acid, as per following formula:

$$NaCl + NaHCO_3 = Na_2CO_3 + HCl.$$

It is, undoubtedly, the characteristic secreting power of the epithelial cell to diffuse the products of this decomposition in a manner that the more alkaline salt will be returned to the blood, while the acid becomes part of the gastric secretion.

It is a peculiar fact that the peptic glands of the pyloric region, which distinguish themselves even macroscopically by their paler color, secrete alkaline fluids, which, however, when acidulated with HCl, have marked peptonizing power. When comparing the anatomical structure of the peptic glands of the pyloric and the non-pyloric region of the stomach, we find that the former have no ovoid, often called peptic, epithelial cells which we find in the tubules of the latter. It seems fair from this to deduce that the ovoid cells of the peptic glands secrete the HCl, as already pointed out by Heidenhain.

I have recently been able to arrive at similar deductions from experiments conducted with Dr. E. P. Davis at the Philadelphia Hospital. In a number of examinations of the gastric juice of normal infants no hydrochloric acid was found present therein,

[1] Read by invitation before the Atlantic County Medical Society, Atlantic City, N. J., September 4, 1889.

while coincident with my observations it was stated that the tubules of the peptic glands of the infantile stomach have no ovoid cells.

Ludwig and Ogata deduce from experiments on dogs on which resection of the entire stomach had been practised, as well as from some in which the pylorus had been occluded and the animals fed by a duodenal fistula, that the stomach was not absolutely necessary as far as digestion was concerned, either as a receptacle for food or as a generator of peptic fluids. Though these experiments of Czerny, Ludwig, and Ogata prove beyond doubt the possibility of nutrition without the stomach in the dog, the predigestion of food in the stomach is certainly indicated by the time it remains there, the changes it undergoes while there, and the absorption of peptonized food directly therefrom. That the stomach should only slowly rid itself of its chyme cannot possibly be only to the end of rendering it antiseptic by contact with its acid secretion, when the powerful peptonizing action of the chlorhydric solution of its secreted albuminoid principle is so well established. That different foods are much more readily acted on by the gastric juice and passed from the stomach, as shown by Beaumont, would also tend to establish the importance of gastric digestion for the nutritive process, even if impairment of the normal gastric digestion did not give rise to special pathological conditions quite characteristic as well as important in their effect upon the general nutrition of the human organism.

Before proceeding to the consideration of the typical diseases of the stomach, their pathology, diagnosis, and treatment, after having learned the special digestive function of the stomach, it is well first to study, as a general pathological condition, the perverted function which must arise more or less from all gastric disorders, and which, as an impairment or lack of the peptic act, is, therefore, termed "dyspepsia." Modern pathology recognizes the fact that gastric digestion is a purely chemical process due to various influences upon the secretory apparatus of the stomach, and the "chemical dyspepsia" has, as such, been proclaimed in the last three German Congresses for Internal Medicine, by von den Welden, Leube, Riegel, Ewald, Boas, Edinger, Jaworsky, etc.

Dyspepsia.

The chemical changes which take place in the stomach under abnormal conditions are the variable composition of the gastric secretion, owing to the increased, diminished, or totally absent quantity of hydrochloric acid, for so far no absence of pepsin has been established in any of the gastric secretions yet examined, and all of them have answered the physiological digestive test if admixed with hydrochloric acid.

The diagnosis of dyspepsia, as practised to-day, is the consequence of, and was developed from lavage of the stomach, as introduced by Kussmaul about twenty years ago, and the close investigation of the matter thus washed out. Previously the contents of the stomach and its secretions were judged principally from the vomited matter, but as this is a pathological product, it cannot give any correct idea of the possible functional ability of this organ. The ingesta, besides largely diluting the gastric secretion, make its chemical examination very uncertain and unreliable. The withdrawal of the gastric secretion when its digestive power is the greatest, is necessary at certain periods which have been ascertained by experiment and observation. This has to be done also at a time when the presence of ingested matter shall not render the withdrawal impossible. Without dwelling on the different experiments to ascertain this period, it is now generally accepted that a special meal should be given, after which, at a certain time, the gastric secretions are withdrawn. The early meal generally employed for this purpose is known as the trial breakfast, which consists of a few pieces, altogether about two to three ounces, of bread or bun and a glass of water or a cup of tea. Jaworsky and Gluzinski, relying on the observation that a soft-boiled egg disappears from the normal stomach in one and a half hours, use this instead of the above-mentioned trial breakfast. At times, however, and especially under pathological conditions, it is found that the egg is not peptonized in that period, and then, by clogging the tube and the now proven union of the free hydrochloric acid with the albuminoids, the withdrawal is rendered difficult and the results inaccurate. To obtain the gastric juice from four to five hours after a more copious "trial dinner" has no advantage, and the "trial breakfast," after all, is the one relied upon.

Ewald and Boas express the gastric juice by epigastric pressure, about one hour after the trial breakfast, when it is known that in the normal state it is strongly acid from hydrochloric acid, the lactic acid having disappeared, and only continuing to be present in abnormal conditions. To express the gastric juice has disadvantages which may be readily avoided by the use of a suction apparatus. Germain Sée recommends a Potain aspirator for this purpose, partial exhaustion only being made, but an ordinary syringe answers the purpose very well, as the quantity for chemical analysis need only be very small, from one to two drachms sufficing to that end. The tube employed for withdrawal of gastric juice is a small-sized, ordinary stomach-tube, having two fenestræ, and, in the cases of infants and children, I have frequently used simply a small, soft-rubber catheter.

After the introduction of the tube in the usual manner, the fluid is withdrawn by slowly drawing

out the piston of the syringe. A sufficient quantity is recognized by a small glass-tube connection in the rubber one; the tube is then carefully withdrawn and emptied into a small glass vessel. The liquid so obtained is next filtered and tested, to ascertain if acid or not, with neutral litmus paper. When the acidity is thus established, the amount of acidity is determined by acidimetry with a decinormal solution of sodium hydrate, litmus or phenolphthalein being used as indicator. Five cubic centimetres of the filtered gastric juice are neutralized with decinormal solution of soda, as stated above, and the total acidity is expressed by multiplying the result by twenty, thus giving the number of cubic centimetres of one-tenth normal soda solution necessary to neutralize one hundred cubic centimetres of gastric juice.

After this is done, the chemical character of the acid is investigated. To this end the lactic acid test of Uffelmann may be applied. This consists of a two per cent. solution of carbolic acid to which a few drops of neutral ferric chloride are added, sufficient to produce a steel-blue color. When this is added to some of the filtered gastric juice it will be decolorized if the acid is pure hydrochloric; if lactic acid is present together with hydrochloric, the color will be changed to a yellowish tint, and if the lactic acid is in excess, it may even assume a reddish-yellow; whereas, in the absence of hydrochloric acid, it will have a more greenish tint. Though this seems to answer the purpose, it only shows the presence of lactic acid, without giving a distinct idea as to the presence of hydrochloric acid.

For the purpose of showing the latter, Laborde proposed the use of methyl-violet; a watery solution of this is promptly changed by HCl to a greenish-blue color, but is not affected by lactic nor the fatty acids. It has, however, the disadvantage of being not sufficiently delicate, and the color-changes with weak acidulous fluids are not distinct enough to judge of small amounts of HCl. To test with it, some of the filtered gastric juice is placed in a small glass vessel (watch-crystal) placed upon white paper, and the test solution is allowed to drop on the side of the vessel and commingle with the fluid, when the change of color can be plainly observed against the white background. In a series of experiments to ascertain the limit of delicacy of these tests for HCl, I have found that the methyl-violet could detect in this manner 1 part of HCl in 2500 parts of water.

The next test, superior in delicacy, is a saturated aqueous solution of tropeolin; this yellow solution, when applied for the examination of gastric juice in the manner described for methyl-violet, will change to a beautiful red, or brownish-red with HCl, is but a little darkened by lactic acid, and very slightly so by the fatty acids. I have ascertained its limit of detection of HCl to be 1 to 3500, while 1 to 500 is the greatest dilution of lactic acid that will darken its color, and it is not affected by a 1 to 100 dilution of acetic acid.

A more recently introduced reagent is the phloroglucin-vanillin. Germain-Sée has made extensive experiments with this, and while it does not indicate organic acids, he claims for it a delicacy sufficient to indicate as little as 1 to 20,000 of HCl—a claim, however, which I have not been able to substantiate entirely from my own experiments.

It was found by Wiesner that if a pine stick was dipped into a phloroglucin solution, and was then touched with strong HCl, it turned a dark-red color. This reaction is caused by the presence of vanillin in the pine wood; and, therefore, this was substituted for it. The test is composed as follows: 2 grammes phloroglucin and 1 gramme vanillin dissolved in 30 grammes absolute alcohol. This yellowish solution gives at once with a stronger mineral acid a dark-red color with deposition of red crystals. To apply this test to weak acid solutions, such as the gastric juice, the fluid must be evaporated at a moderate heat, not reaching the boiling-point of water, to drive off the water and leave the HCl of sufficient strength to act on the reagent. To this end a few drops of the test are mixed with a similar quantity of the filtered secretion, and then slowly evaporated to dryness. If HCl is present the dry residue assumes a red color, or if present in very small quantity may show distinct red outlines only. In my hands this test, certainly a very valuable and delicate one, failed to indicate more than 1 part HCl in 10,000 parts.

The red Congo paper, as proposed by Prof. Riegel, is a most delicate reagent, and easy of application. It is readily turned of a bright greenish-blue color by HCl, but is also affected by lactic acid, which changes its color to a dark dirty-blue; and acetic acid will darken it with a bluish tinge. With this reagent, as obtained from Merck in Darmstadt, I was able to detect as little as 1 part of HCl in 20,000 parts of water; and while 1 part of acetic acid to 3000 water gave a slight change in color with bluish edges, 1 of this to 5000 did not affect it in any manner; 1 part of lactic acid in 5000 water was indicated by it in traces, but 1 to 6000 failed to elicit a change in its color.

It is thus seen that the latter is perhaps the most delicate reagent we have, not alone for HCl, but as an indicator of general acidity, and that when it fails to indicate the latter a total anacidity may be fairly claimed. When it indicates acidity, the application of the other tests may become necessary, not alone to ascertain the character of the acidity, but to approximate the degree to which HCl may be present in cases of subacidity. The gradation

and limits of these reagents, as pointed out by me, may be readily utilized to this end by dilution of the secretion up to the point where either of the above tests fail, and computing the HCl by the amount of the dilution.

The excess, normal presence, diminution, or absence of HCl being thus established, the digestive power of the gastric juice is now ascertained by the physiological test. To this end a small piece of coagulated egg albumen of about 7 mm. diameter and 1 mm. thickness is digested at the temperature of the body, and the comparative time necessary for its solution noted. With normal secretion this should be complete in from one to one and a half hours, whereas under abnormal conditions a much longer period and the addition of HCl may be required.

To classify the different phases of chemical dyspepsia, they can be conveniently arranged as hyperacidity, subacidity, and anacidity.

Hyperacidity is the overproduction of HCl by the peptic glands, the amount reaching as much as 0.4 to 0.6 per cent. of the peptic secretion. Its *etiology* seems still obscure, and may be attributed perhaps to the chemical condition of the blood, and to the concentric rather than peripheral stimulation of the secretory glands, and it is a fact that at times it is found irrespective of food ingestion. While its *symptoms* are quite characteristic, consisting of pyrosis, acid eructations which perceptibly affect the teeth, occasional vomiting, and ptyalism, under such conditions commonly termed water-brash, its *diagnosis* is readily made out with the tube and subsequent acidimetry, and confirming the character of the acid with methyl-violet, which is promptly changed to a distinct greenish-blue.

As a chemical indication for the *therapy* of acid dyspepsia or hyperacidity, alkalies must rank first and foremost; amongst them the sodium bicarbonate deserves principal consideration in massive doses of from 30 to 45 grains every four hours, and before meals. Alvine evacuations, which are more or less suppressed in this condition, should be freely promoted by Carlsbad salts, or by appropriate preparations of rhubarb in laxative doses. Hot potations, which are often lauded in this connection, have, in my experience, proven of little avail, but free lavage with borax or sodium bicarbonate solution gives the greatest relief. As physiologically indicated the diet should consist of proteid substances, while carbohydrates must be studiously avoided.

Subacidity. *Etiology.*—While in hyperacidity it was an excess of HCl which caused rather gastric distress than suppression of the peptic act, subacidity is generally observed in the catarrhal conditions of the gastric mucous membranes which are caused by improper food, excesses in drink or chemical irritants, and where, through irritation, the mucosa is hyperæmic and secreting abnormal quantities of alkaline mucus, diminishing the ostia of the peptic glands, and admixing the former with the gastric juice proper, thus preventing its proper action on the food-bolus. The common acute indigestions of our summer months, attributable to excessive drinking of iced beverages, belong to this class.

The *symptoms* are anorexia, thirst, slight fever, a sense of pressure and fulness in the epigastrium, occasional vomiting, and belching of gas, with eructations of fermenting food. A dry and coated tongue is generally observed in this condition, together with a bitter taste in the mouth. The bowels may be loose or bound, and by a progressive advance of the catarrhal process to the duodenum it may be followed by icteroid appearance.

Treatment.—This class of dyspepsia calls for rapid evacuation of the stomach, either by tube or emetic, followed by local sedatives, such as bismuth and soda; while after subsidence of the mucous hyperæmia and a continuance of subacidity, ten to fifteen drops of dilute HCl in water prove of service given after food. During the febrile stage small pieces of ice by the mouth and iced milk diluted with some effervescent alkaline mineral waters prove most grateful and serviceable.

Chronic Gastric Catarrh.

The persistence or frequent repetition of ingestion of the causative elements of the acute gastric catarrh cause a chronic state commonly met with in subjects, termed "chronic dyspeptics," and, as the chronic gastric catarrh, is the cause of subacid disturbances of the digestive function. This may be, and often really is, gastro-enteritis; and, again, it is dependent at times upon other diseases and, therefore, only secondary in character. The cause of disturbance of the chemical composition of the gastric secretion hence must be looked for either in the altered chemical composition of the blood or in the changed anatomical relations of the glands.

The gastric mucous membrane in this affection is heavily coated with a grayish-white material, consisting largely of cast-off epithelium; the odor from the buccal cavity is, from this cause, more or less offensive, and the mucosa beneath the coating is red and hyperæmic. According to the stage of its existence, the mucous surfaces may be smooth or atrophic, and there may be an accompanying atrophy of the peptic glands and an increase of connective tissue between them. Not infrequently hyperplasia of the mucosa exists, diminishing the ostia of the peptic glands, the hyperplasia extending at times even to the submucous tissue.

The main result of these anatomical changes consists in the reduction of the amount of HCl in the secretion, and with it the diminished digestive power and an insufficient inhibition of bacterial develop-

ment, in consequence of which fermentation of the ingesta ensues, with copious eructation of gases and the formation of lactic, acetic, and other acids. In cases where the absence of HCl is very marked, the fermentative processes may cause vomiting, and the ejecta will often reveal to microscopic inspection yeast fungi and sarcinæ ventriculi, which are, however, of no special pathological consequence.

A feature of the chronic gastric catarrh is the impaired peristalsis of the stomach. This is dependent on the diminished amount of HCl present, as we know that in the normal stomach this acid is the principal exciting cause of gastric peristalsis. In consequence thereof dilatation results, and the degree of subacidity becomes more and more marked until almost entire anacidity prevails, as I had occasion to observe in several instances of chronic gastric catarrh during a recent investigation of a series of cases of this kind at the German Hospital of Philadelphia, made by myself and the medical resi dent, Dr. Gerlach.

As the physical examination of the stomach offers no characteristic points for *diagnosis*, the latter cannot well be established without the chemical examination, together with due consideration of the subjective and objective symptoms and exclusion of such pathological conditions which stamp the dyspepsia as secondary to some other affection.

The *treatment* of the chronic catarrh of the stomach as a primary affection should be largely dietetic, avoiding all food that is irritant, bulky, or slowly acted on by the gastric secretions. Thus, carbohydrates should be avoided, also fats, and principally alcoholic beverages. Milk, broths with raw eggs broken and stirred into them, and toast, should, in severe cases, constitute the principal food. As the tardy gastric digestion will favor fermentative changes, which in turn act as irritants and favor the accumulation of mucous secretion, the removal of undigested food, together with such bacteria as would incite decomposition *de novo* in freshly added food, is indicated in all such cases, and calls for mechanical treatment by lavage, which, though little practised in this country so far, has often worked wonders with chronic dyspeptics.

Amongst the remedial agents the chemical indication for the use of HCl would certainly be foremost, to correct the subacidity and promote the peptic process. When lavage is practised this indication will generally hold good, but when the milder symptoms do not indicate the use of the tube it will do no good. The reason for this is the large amount of mucus which is coagulated by the acid, and by enveloping the food particles prevents them from being acted upon by the gastric secretions. In these cases the alkalies, and among them the sodium bicarbonate, should be used, together with the vegetable bitters to excite active secretion; of these the tinc. gentian. comp., tinct. nucis vomic., tinct. colombo, etc., will prove of good service. Gastric antiseptics and antiferments can hardly be administered in sufficient quantity to do good, and very few, if any, are germicidal enough to correct an already fermented food-bolus. The constipation, sometimes so marked in these cases, is best overcome by Carlsbad salts or by some of the laxative mineral waters, or in more obstinate cases by pil. rhei comp.

Nervous Dyspepsia.

The influence of the nervous system upon the gastric digestion has been regarded as of great importance and has led to the special classification of "nervous dyspepsia."

That the innervation of the stomach may influence the gastric secretion, and that hyperacidity or subacidity may thus arise, is not to be doubted, but that special nerve influence could pervert the chemical act of digestion with normal secretion in the stomach any more than in the retort is not reasonable. The only neuroses appreciable to our present state of knowledge must be those of either sensory or motor disturbances. The reflexes causing intense neuralgic pains of the stomach may depend primarily upon perverted digestion, with or without motor implication, and are, as such, known as "gastralgia." In neurotic patients they may develop, even without peptic disturbances, from external influences upon a morbid mind; but that with normal gastric secretion, the chymification of food should be interfered with by nerve influence can only be explained by the interference of reflexes with the motor innervation—*i. e.*, gastric peristalsis—accompanied either by pain or emesis, or both. The many subjective symptoms of the so-called "nervous dyspepsia" are certainly pure psychoses and cannot be classed with gastric diseases. It is doubtful if migraine is of gastric origin or due to intestinal indigestion, and also if the gastric neuroses, such as vertigo, etc., do not all, more or less, arise from this source.

The *treatment* of the neuroses of the stomach, as indicated by the character of the affection, must be either anæsthetic or else directed to the motor innervation. In the pure gastralgias, morphine hypodermatically will prove all that is requisite; in increased peristalsis with convulsive contractions and vomiting the bromides or chloral, or both, will meet the issue, while in atony of the muscularis nothing will prove as serviceable as nux vomica, calisthenics and the cold douche or surf-bathing. The subjective symptoms and psychoses, electing the gastric function for the toy of a morbid mental state, will yield to moral treatment and proper hygienic conditions if at all, but not to pepsin and kindred medication.

ULCER OF THE STOMACH.

Of the gastric diseases not directly arising from perverted peptic function, but at times seriously affecting it, is ulcer of the stomach.

The *etiology* of this disease is as yet obscure, although experimentally it has been produced by embolic processes of the vessels of the gastric mucous membrane. Though its primary cause is not known or to a certainty proven by the experiments mentioned, there seems to be no doubt that it is indirectly caused by autodigestion of the affected portion of the stomach. The fact that the normal stomach resists the digestive power of its secretions has been variously attributed to the alkalinity of the blood circulating through it and, also, to the vital resistance of the living tissue against the chemical process. The latter seems such a speculative assumption, based upon an absolutely undefined factor, that it might be far better to adhere to the more rational theory, which is certainly substantiated by experiment and the observation that the dead stomach as well as that cut off from circulation, digests itself.

The gastric ulcer is of circular outline and spreads as well to the periphery as to the fundus, so that with clean-cut edges it narrows down to a funnel shape. The fact that it is generally clean is due to the erosive action of the peptic secretion; it may be superficial only, or reach the muscular and serous coats, even perforating the viscus entirely. While generally solitary, it is multiple at times, and, though principally met with in the pyloric region, it is also occasionally found in the lesser curvature and, as a rule, on the posterior wall, which accounts for the agglutination of the stomach in such affections with neighboring viscera. The ulcerative process and erosion may affect smaller or larger vessels and thus give rise to the characteristic hæmatemesis.

Symptoms.—Though ulcus ventriculi may not in all cases be accompanied by characteristic symptoms, there are a large number of cases which exhibit phenomena to warrant suspicion of the existence of ulcer. Of these, localized pain is, perhaps, the earliest, with gastric irritability and, probably, vomiting. The pain may be localized or diffused, or of a neuralgic character, referred to the epigastrium or back, or radiating; it is often relieved by a change of position, and, if this results from recumbency on the left side, its location is most probably in the pylorus. The localized pain increases with ingestion of coarse food, and, if found circumscribed on pressure, this would also form an important factor in the diagnosis. Though the emesis accompanying these subjective manifestations is of some additional diagnostic value, it is by no means a frequent concomitant and not characteristic of ulcer, unless accompanied by blood in sufficient quantity to stamp it as hæmatemesis.

The blood from erosion of a vessel by gastric ulcer is, however, not always ejected from the stomach, but appears at times in the dejecta, imparting to them a dark and tarry appearance. The vomited blood is generally clotted, mixed with food particles, and acid reaction in contradistinction to the light, frothy-looking blood of hæmoptysis. Gastric hemorrhage may range from a few ounces to several pints, and, when very copious, may be, and occasionally is, the cause of fatal results. The dyspeptic symptoms of gastric ulcer are of no diagnostic value, and arise from accompanying conditions rather than the disease itself; but a most general symptom connected with it is the hyperacidity described by Riegel, and since confirmed by others; this is of great importance in the indication for treatment.

The *prognosis* of ulcer of the stomach may be said to be favorable in the majority of cases, as to direct results. The indirect sequel from cicatricial stenosis of the pylorus we will consider under the head of dilatation. The incidental perforation or exsanguination are factors which make the prognosis very grave, if not necessarily fatal, but fortunately arise in isolated instances only.

The *therapy* of ulcer of the stomach, as indicated by its pathology, would preclude, before all, the ingestion of solid food and, in fact, of anything that would excite or promote peptic secretion. I consider milk diet in such cases with hyperacidity as little calculated to benefit the patient, as the firm coagula of acid casein not only stimulate peptic secretion but offer great resistance to gastric peristalsis and still further obstacles to subsequent pancreatic digestion, thereby causing intestinal indigestion and thus defeating the very object of nutrition. Broths, with raw eggs broken and stirred into them, which are capable of uniting with free hydrochloric acid and of diminishing the peptic power of the free acid, as recently proven by Felix O. Cohn, offer certainly a more rational diet, readily digested and assimilated. I have succeeded better with total abstinence from food and rectal alimentation than by any other method. Thirst is to be quenched with ice, pain controlled by morphine hypodermatically, while the hyperacidity is overcome by sodium bicarbonate in massive doses.

Absolute rest is of utmost importance both physically, mentally, and as a matter of course as far as the stomach is concerned. Hot fomentations to the epigastrium arrest paroxysms of pain, while ice-pills per os and the ice-bag locally will assist in the treatment for hemorrhage. The latter is best combated by hypodermatic injections of ergotin or scruple doses of gallic acid frequently repeated. Nausea and vomiting are met with ice-pills, chloral, creasote, or Lugol's solution. Perforation and the results therefrom may possibly be benefited by surgical treat-

ment, but too little as yet is known regarding this to base much hope on its success.

DILATATION OF THE STOMACH.

Dilatation of the stomach is a pathological condition generally, if not probably always, accompanied by subacidity, and in a large number of cases with anacidity.

Only a minority of cases of this kind are primary dilatation—*i. e.*, that do not depend upon some other morbid affection of the stomach; the majority are secondary, in so far that they are consequent upon stenosis of the pylorus, which in turn may be either benign or malignant—the former arising from cicatricial contraction after ulcer, the latter due to the presence of carcinoma in that region. There may be also stenosis from mechanical pressure of near-lying tumors (floating kidney, Bartels), which, in turn, like all obstructions in that locality, occasion dilatation of the stomach.

Gastric dilatation without pyloric obstruction is sometimes noted in, and consequent upon, chronic catarrh of the stomach, but never occurs then in that degree as in the variety resulting from the former cause. It depends upon paresis of the muscular coat resulting from general debility or overdistention by ingested matter, and is frequently noted in those who indulge to excess in the pleasures of the table and the cup. I have had occasion to observe it more in connection with the chronic gastric catarrh of beer-drinkers than of any other class of patients, and it is also claimed to be frequently found among diabetics.

The *pathology* of gastric dilatation is to be considered as similar to that of cardiac dilatation in aortic obstruction. The muscular fibres of the stomach, to overcome the pyloric constriction, first become hypertrophied; the accumulation of food soon produces paresis of the muscular coat and dilatation results, which increases in the same measure as the chemical peptic act is diminished, and the fermentative changes of the food-bolus produce irritation and inflammation of the mucosa. The latter, under such conditions, fails to secrete a sufficient amount of hydrochloric acid, which is the excitant to gastric peristalsis. As a consequence of overdistention, the mucous coat suffers anatomical changes, the ostia of the peptic glands—which at first appear almost hypertrophied and extend beyond the surface of the mucosa—soon atrophy, and with it the secreting power of the gland becomes less and less.

It was thought at one time that anacidity was pathognomonic of gastric carcinoma, but that has been certainly disproven, and it can only be possible when pyloric cancer, and consequent obstruction, produces dilatation of the stomach. Any considerable dilatation must necessarily result in subacidity, and if existing for some time and in increasing ratio, or from complete pyloric stenosis, it must result in anacidity. This has been disputed and HCl has been claimed as being present in not merely distended stomachs but also in the overdistention or complete dilatation from pyloric obstruction, but it seems unlikely, and when we consider the diagnostic difficulties for defining distention, or even sometimes complete dilatation, the error may be readily looked for rather in the diagnosis than in the pathological condition. We may justly assume that anacidity is not a symptom accompanying any special gastric disease, but in all probability always results from complete dilatation from whatever cause this may happen. While in the functional anacidity from gastric catarrh, etc., this may exist for the time being and is, no doubt, also the result of dilatation, it being a paresis of the muscular coat rather than a paralysis of the fibre as in complete dilatation, the chemical character of the gastric secretion can be restored by a removal of the vicious element.

The *symptoms* of gastric ectasis are those of apepsia generally, anorexia, gastric pressure, eructations, pyrosis, and vomiting. The latter is somewhat characteristic, as it takes place at longer intervals only, when the ectasis has assumed great proportions and fermentative changes exert their irritation upon the mucous membrane. According to the amount and quality of food taken, it may happen only once in twenty-four hours, or in three to four days and even longer periods. My friend Dr. J. M. Barton ingeniously ascertains the number of meals comprised in the emetic act under such conditions, by giving a number of raisins with each meal and counting their number when rejected from the stomach. To arrive at the degree of stenosis he gives both raisins and a few currants. If the latter are not ejected in the vomit he concludes very justly that the pylorus is partly pervious and deduces the amount of constriction from the size of the currants. The ejected matter is usually copious, is readily vomited without much nausea or straining, and patients feel a great sense of relief after it.

The *diagnosis* is not always as readily arrived at as might be judged from the number of mechanical means for this purpose. The objective examination by palpation and percussion leads in well-marked cases at times easily to a satisfactory conclusion, especially if the stomach is filled by fluids or gases. To that end it is often of great service to give in different potions about thirty grains of sodium bicarbonate and tartaric acid, when, as a rule, the inflated stomach may be palpated with facility. If, in addition to this, a quantity of water, about eight to twelve ounces, is swallowed and the line of dulness by percussion is located below the umbilicus, the diagnosis is pretty certain. Adhesions from perforating ulcer or carcinoma may, however, embar-

rass the result under such circumstances. Perhaps the most satisfactory method for ascertaining the capacity of the dilated stomach in complete pyloric stenosis is to fill the stomach with water through the tube and to measure the fluid as siphoned out therefrom. In atonic dilatation or with perforating ulcer or carcinoma this, also, is valueless. The examination of the stomach for dilatation by means of the sound does not possess the value claimed for it, as displacement of the viscus may simulate the pathological condition in question.

The general condition of the patient suffering from gastric ectasis is always more or less impaired; emaciation rapidly takes place; the bowels are obstinately constipated and will not be open for days and weeks; the urine is generally small in quantity and of neutral or alkaline reaction. The total absence of hydrochloric acid from the stomach in connection with the other symptoms above enumerated would certainly point very strongly toward an existing dilatation as probably arising from pyloric obstruction. Functional dilatation may be accompanied by subacidity, and in these cases the existence of dilatation together with the degree of ectasis can be arrived at satisfactorily only in a minority of the cases.

The *prognosis* of atonic or functional dilatation of the stomach may be viewed as favorable—*i. e.*, readily yielding to proper therapy. Gastric ectasis from cicatricial pyloric stenosis is more serious, but with proper management much can be done toward keeping up nutrition and preserving life. The recent operative treatment in this condition, as practised by Loreta in Italy, and Bull and Barton in this country, has been so successful that a great future may be promised for it. The prognosis of dilatation from carcinomatous stenosis of the pylorus is most unfavorable, though pylorectomy has produced some favorable results.

The *treatment* for atonic gastric ectasis is one that depends largely on a proper diet. Albuminous substances, such as eggs, broths, or scraped meat, should be freely exhibited, followed by dilute hydrochloric acid with strychnine or nux vomica. Carbohydrates should be prohibited, nor should milk or other beverages be taken in quantities; saline laxatives are best indicated to keep the bowels solvent; the faradic current applied to the epigastrium will prove of vast value; the catarrhal condition should receive attention, as pointed out under that head.

In the graver or secondary dilatation the treatment must depend upon the removal of the accumulated food by means of the stomach tube and the daily repeated lavage. While the pyloric stenosis is not directly benefited by this, the hyperæmia and œdema accompanying it can be much relieved by this treatment. In a case now under my care in the German Hospital, complete stenosis no doubt existed; no alvine dejecta had passed for about two months, all of the food taken was vomited at intervals of from one to two days; the patient's weight from 156 pounds sank to 89 pounds, and corresponding debility was manifest. By frequent lavage and the administration of albuminoid food with HCl, and nutritive enemata of carbohydrates (glucose), the patient gained in strength and weight. At one time during the treatment he washed out through the tube an apple-seed, though he had not eaten apples for two months past. Alvine discharges soon became regular, and are now formed, while the patient's weight to-day is 129 pounds.

Though I do not regard the stenosis in this case as cured, the obstruction arising from congestion or œdema must have been certainly relieved to admit of good gastric digestion, and the dilatation has undoubtedly been improved, as the gastric secretion is beginning to show traces of HCl, and the patient has appetite and digests food without medicinal aid.

That all of these cases should ultimately be treated in a surgical way, I fully believe, and when I consider the good result achieved Dr. Barton in his recent case, patients should be encougaged to that end. Much, however, can be done medically to relieve the patient, and this should be exhausted or done preparatory to operative interference. It has been my habit in such cases to wash out the stomach daily with 3 to 4 pints of a dilute solution of borax, to give broths with egg and scraped beef as nourishment, followed by HCl with nux vomica; and to administer enemata of from 4 to 6 ounces of glucose thinned with a little warm water and admixed with ½ to 1 ounce of beef peptones.

In the dilatation depending upon carcinomatous stricture of the pylorus, little is to be hoped from treatment of any kind other than intended to palliate the pain and relieve the most urgent symptoms.

Cancer of the Stomach.

Cancer of the stomach is the gravest and most fatal of all gastric affections. The *etiology*, like that of all malignant neoplasms, is entirely obscure in this affection as well, and though Hauser called attention to the atypical epithelium arising from cicatrices of gastric ulcer, no direct connection between the two has as yet been established. It occurs generally between the ages of forty and sixty, but much younger persons are found suffering from it at times; the hereditary tendency has been received with some credence; the duration may be from one to two years, rarely more.

Gastric carcinomata are quite frequent, and it is claimed that they comprise about one-third of the total number of malignant growths. They occur more generally in the pyloric region, next frequently in the lesser curvature, but are also found in the fundus and cardia. Arising from the mucous

coat they present either as circumscribed tumors or diffuse infiltrations progressing to the submucous and muscular coats, and are sometimes the cause of adhesions to neighboring viscera. The scirrhous, medullary, and colloidal are the principal varieties observed; they are, as a rule, in the advanced state, broken down on their surface, which is clean, owing to the digestive action of the peptic secretion.

Symptoms.—Their effect upon the patient marks a steadily downward course, leading to rapid emaciation, cachexia, and anæmia; the dyspeptic symptoms are not always alike, but are probably the first to occasion complaint—consisting of anorexia, gastric pressure increasing to pain, and in many cases, but not in all, there is characteristic vomiting. Hæmatemesis is perhaps more frequent, but not nearly as copious as in ulcer, and the small quantities of blood are generally reduced to hæmatin, which gives the ejected matter the appearance of coffee-grounds. To confirm the presence of blood the hæmin test should be made, and the Teichmann's crystals of hæmatin hydrochloride developed for microscopic recognition. The vomited matter rarely, if ever, shows cancer cells or particles characteristic of cancerous structure, and the sarcinæ, etc., are seen, as in other cases of dilatation or apepsia.

An important symptom accompanying many cases of gastric carcinoma is the anacidity frequently observed in connection with it. While it was held by von den Welden that this is characteristic of cancer of the stomach, it was found that in some cases of carcinoma there was not alone no anacidity, but even hyperacidity. The ingenious experiments of Riegel, which demonstrated the impairment of normal gastric juice by the proteid character of carcinomatous fluids, are negatived by the recent experiments, which show that all albuminous substances will cause the same result. In my opinion only such cases of gastric cancer can produce anacidity as cause pyloric stenosis and dilatation in consequence thereof; and that carcinomatous disease in other parts of the stomach may not only not diminish the HCl acidity of the gastric secretion, but like gastric ulcer may actually increase it—an important point in the diagnosis of location.

The palpation of the stomach leads often to the *diagnosis* of tumescence directly attributable to malignant disease, but the absence of tumescence is by no means a proof of the non-existence of the former. Percussion of the stomach is of little, if any, positive diagnostic value. The alvine discharges are much inhibited in the pyloric obstruction from cancer, but otherwise offer no diagnostic points, nor does the urine. The heart and pulse bear the general character of anæmia and inanition, but have no other bearing on the pathological condition.

As we have already indicated, the *treatment* of gastric carcinoma can at best be one intended to palliate the suffering and meet the symptoms. These latter have been already referred to in the treatment of dilatation from pyloric obstruction, to which should be added morphine hypodermatically for pain; and for the obstinate vomiting, ice, chloral, creasote, or Lugol's solution. Lavage must here also be the sheet-anchor; proteid diet, rectal alimentation, and supporting treatment of all kinds, and stimulants, especially effervescent wines, are about the only means to prolong the existence of suffering to which these patients seem condemned.

It is as yet a matter of doubt if operative interference in pyloric carcinomata will prove of great value. That some of the cases so treated have done well throws out a ray of hope, which, even if it does not realize curative results, for a time relieves the sufferings incidental to this disease.

333 SOUTH TWELFTH ST., PHILADELPHIA.

SOME THOUGHTS ON SURGICAL SHOCK, WITH SPECIAL REFERENCE TO BRAIN AND SPINAL OPERATIONS.

BY F. X. DERCUM, M.D.,

INSTRUCTOR IN NERVOUS DISEASES, UNIVERSITY OF PENNSYLVANIA; NEUROLOGIST TO THE PHILADELPHIA HOSPITAL.

THE writer has had the opportunity of witnessing many of the remarkable brain and spinal operations lately performed in Philadelphia, and the following thoughts have arisen as a result of this experience. It is not intended to encroach upon the field belonging properly to the surgeon, but merely to make a few suggestions that may possibly be of value in the desperate cases occasionally submitted to the knife.

Observation shows that operations upon the cerebrum, the cerebellum, and the cord are, as a rule, attended by the most profound shock. Evidently this shock is the greatest danger which the surgeon has to meet. Indeed, in the various fatal cases which the writer has seen, it was the chief, if not the only, cause of death. It is so formidable that every resource at our command should be exhausted to meet it; nothing should be neglected. In some cases a hair might turn the scale, and it is for this reason that the following suggestions are made.

With regard to the special preparation of the patient the judgment and experience of the surgeon should be deferred to. I should like, however, to direct attention to a point the value of which was long ago recognized by Travers[1] and which was more recently reiterated by Jordan.[2] It is to place the patient in a condition of rest and quiet by putting him to bed for several days or a week before the operation. This method appears to me to be of really great value. Certainly it promises to diminish the general nervousness and irritability of the patient. It promises to calm and steady and to im-

[1] Travers: Constitutional Irritation, 1827.

[2] Jordan: Hastings' essay, on Shock.

prove all of the various functions. While it soothes, it at the same time elevates the general level of vitality and in a measure simulates a brief course of rest-cure.

Further, by being in bed the patient gradually becomes accustomed to the idea of being sick. Even the thought of the operation becomes more and more familiar, and, under the toning influence of a properly trained nurse, loses more than half its terrors. Again, these preliminaries give abundant opportunity for a cheerful acquaintance with the surgeon and permit a grateful confidence to spring up in the heart of the patient. By this means, the psychic element of shock, so potent for ill, and which, I fear, frequently receives too little consideration, may be largely diminished.

According to circumstances, the rest-cure may be still further simulated by the addition of massage and even of faradism. Forced feeding to within twenty-four or forty-eight hours of the operation may also be carried out. Strict isolation is, of course, uncalled for, but emotional friends and relatives should be excluded. No one should be permitted to see the patient unless by the consent of the doctor or a responsible nurse. To patients who have been for some time bedridden, and to those in whom from the very nature of their affection the general nervous tone has become much depressed, these suggestions are especially applicable.

Turning now to the immediate prophylaxis of shock, it has occurred to me that the hypodermatic injection of strychnia just before the operation would be of value. I am not aware that this use of strychnia has thus far been advocated. To some extent, but much less than it should be, it has been used in the treatment of the fully established shock. Evidently if shock be due, as there is every reason to believe, to a more or less marked general paralysis of the nervous system, strychnia is strongly indicated. It is its use as a prophylactic to which I especially desire to call attention.

I would suggest that it be used somewhat as follows: According to the nature of the operation, one twentieth to one-tenth of a grain of the sulphate should be injected just as full etherization is reached. Should the operation be excessively prolonged or should shock of great intensity be developed, the dose should be repeated. Its use subsequent to the operation must be governed by the condition of the patient and by the amount already administered.

There can be no doubt that a tolerance to the action of strychnia is to some extent established in shock and that relatively massive doses will be well borne. I should regard one-fifth or one-fourth of a grain in divided doses distributed over several hours as perfectly safe. It is not improbable that in very profound shock even more might be borne.

Its use and its dose previous to the operation must, of course, depend upon the character and probable extent of the latter. In relatively simple procedures it may very properly be omitted, and, if necessary, administered during, or subsequent to, the operation, as the indications arise. For instance, its use is not strongly indicated in interference with the cortex in the frontal or motor regions; provided, of course, that the interference be not too extensive. Observation inclines me to the view that the shock following operations upon the cerebro-spinal axis deepens as we go from the frontal regions of the brain backward to the occipital lobes; further, that it is still deeper in the cerebellum, and reaches its acme of intensity in the cord. If this be true, a ready rule is furnished not only for the use but also for the dosage of strychnia.

It is difficult, finally, to conceive of any condition in which it could possibly be of harm, and only in positively reckless hands could there be any danger whatever.

With regard to the matter of etherization, there can be no doubt that the too free administration of ether is not infrequently harmful and it is very probable that it occasionally plays no insignificant part in the collapse of the patient. The rule that only the minimum quantity of ether necessary to produce and maintain anæsthesia should be used, is to be observed with all possible strictness. In a desperate case this may be one of the apparently unimportant measures that may determine the successful issue, and if possible the services of some one especially skilled in the administration of anæsthetics should be secured.

Passing now to the management of the fully established shock we think at once, in addition to strychnia, of the various cardiac stimulants, alcohol, digitalis, and ammonia. With regard to the use of these drugs I shall have but little to say, as I have elsewhere[1] considered them to some extent.

Alcohol is, of course, of the greatest value, but, as a rule, the patient is nauseated after the operation and unable to retain it, even when mixed with carbonated water or administered in the form of champagne. Hypodermatically it must give way in point of value to digitalis.

If the symptoms of heart failure be at all pronounced, digitalis should be given, and in doses large enough and repeated with sufficient frequency to produce an appreciable effect on the pulse. As in the case of strychnia, there is established in profound shock a tolerance of digitalis so that the latter may be administered in quite large doses. A half drachm of the tincture every half-hour has been

[1] Railroad Shock and its Treatment. Annual address before the Lehigh Valley Medical Society, Aug. 16, 1889. Therapeutic Gazette. (In press.)

given for four hours with the result of saving life.[1] Hypodermatically, ten to fifteen minims should be given, repeated every twenty minutes, until some response is detected in the pulse.

Of ammonia as a remedy in shock I entertain but a poor opinion. Its action is altogether too fleeting, and if used at all it should only be as an adjuvant to the other remedies.

There is, however, one drug that, judging from every indication, should be of especial value, and which, strange to say, is almost unappreciated. It certainly is by far too little resorted to. I speak of musk. Musk—that is, the genuine drug—is not readily obtained and is very expensive, but there is no other drug that promises so much. It acts as a gentle and sustaining stimulant to the nerve centres. It calms and steadies. It quiets the restlessness of the patient, allays the vomiting, and arrests the distressing hiccough. It should be administered after the manner recommended by Dr. H. C. Wood—namely, suspended in a little thin mucilage and by the rectum. In shock, of course, the dose should be relatively large, say fifteen to twenty grains; and a little laudanum, say fifteen drops, may be added with advantage. Opium in full doses, however, should rather be avoided, even in extreme restlessness, as there is good reason to believe that in shock the resistance to opium is much diminished. Exceptionally its use may be counselled, but never without risk.

Another remedy of undoubted usefulness in shock is atropia. As well known, it is a respiratory stimulant and also a stimulant to the vaso-motor nerve centres in general. The patient is, as a rule, bathed in a profuse and exhausting sweat, and in such a case atropia is especially indicated. One-sixtieth of a grain should be given, and repeated, if at all, in diminished dose and at relatively long intervals.

However, one of the most striking and most dangerous symptoms of shock still remains to be combated, and that is, the fall of temperature. The moment we touch the patient we realize how very cold he is—cold and damp. It is always very marked; sometimes the temperature falls as low as 95°.[2] Application of external heat is of the utmost consequence. However, the amount of good accomplished by such appliances as cans and bottles of hot water is very limited. Their action is confined to but small extents of surface, and the effect on the body temperature as a whole is very meagre. The hot bath, which may be resorted to in desperate cases, is very objectionable; first, because it necessitates a large amount of handling of the patient; secondly, because in some cases it may interfere with the dressings; and lastly, because the heat applied is moist and not dry heat. It is preëminently necessary that the heat should be *dry* heat, and the problem arises: By what means can dry heat be applied to a large extent of surface and without inconvenience to the patient?

Some time ago I was called to a patient in collapse during an attack of pleurisy. The temperature had fallen to 96.5° and the general condition was alarming.[1] I at once procured an ordinary hospital water-bed, such as is used for fractures and dislocations of the spine. It was filled with hot water, covered by several layers of flannel blankets, and the patient placed upon it. In a short time reaction set in, and the temperature rose to a little above normal. The result was, indeed, gratifying in the extreme. Certainly no other method promises to yield such excellent and immediate results, and, it seems to me, that in desperate surgical procedures in which profound shock may be expected, the hot-water bed should be kept in readiness and the patient placed upon it as soon as the operation has been completed. Should it be too hot, extra layers of blankets may be first applied. With care, however, and the exercise of a little judgment, a proper temperature may easily be obtained.

Let us suppose, now, that the surgeon is about to perform a serious operation, say trephining of the spinal canal with possible opening up of the dura. How shall he proceed? Let us rehearse a moment the steps that he would take. First, the preliminary rest should be undertaken according to circumstances, as pointed out; secondly, excessive care is to be used in the administration of ether; thirdly, etherization being complete, one-tenth of a grain of strychnia is to be injected hypodermatically, and repeated, if necessary, in the manner suggested; fourthly, the operation being complete, and the shock established, the patient is to be at once transferred to the previously prepared hot-water bed, the head being maintained a little lower than the body. Shock continuing unabated, digitalis and atropia are next to be used hypodermatically, and at the same time musk is to be injected, as suggested, into the bowel. If the latter is not to be obtained, warm strong black coffee is to be used in its stead.

The hypodermatic injection of ether I do not believe to possess much utility. If it acts at all, it must be in a reflex way by the local irritation it produces.

The above thoughts are expressed with all deference to the experience of surgeons, and are thrown out merely as suggestions. Should they result in increasing the percentage of recoveries by ever so small an amount, the writer will feel amply repaid.

THE MINERAL SPRINGS OF COLORADO.[1]

BY CHARLES DENISON, M.D.,
OF DENVER, COLORADO.

(Concluded from page 290)

THE CLIMATE

of Idaho Springs is decidedly stimulating, bracing, and exciting. Like most mountain regions of its altitude, there is an electrical condition of the atmosphere accompanied by high tension and excess of ozone. In these regards, as well as in the greater fickleness of the winds, and the usual lower average temperature, it differs from the climate of the "plains," over 2000 feet below. Otherwise there is a great similarity; that is, as to the uniformly dry atmosphere, the usual gentleness of the wind, and the marked predominance of sunshine over cloudiness. Many residents in the mountains claim that the summers are cooler and the winters warmer than out on "the valley," as the level country along the eastern base of the Rocky Mountains is sometimes called. Since this claim has to be admitted for the summer temperatures, it cannot be so for the winters, because the annual mean for Denver is 49.2° and for Idaho Springs, 45° F. The winters in the mountains may be warmer in proportion to the summers there, but not enough so more than to neutralize the annual difference between Idaho Springs and Denver, of 4.2 degrees.

This is the average of two years' observations at hand, taken by Mr. I. Zeller and Mr. C. E. Barber, of Idaho Springs. While the annual mean for Idaho Springs is four and a half degrees colder than that of Denver, it is only two degrees colder than the average for Manitou.

It is well to remember, when speaking of the average temperatures of such elevated places, that the rule for computing them, as practised by the Signal Service Bureau, involves an injustice, so to speak, to the day-time records, when people are out of doors, in that the cold 9 P.M. observation is doubled and then added to the cold 7 A.M., and the one warm 2 P.M. observation, and the sum divided by four, to get the daily mean. The greater the elevation above the sea, the more is this inconsistency apparent, especially in mountainous sections, where the towns located in the valleys do not begin to feel the sun's influence till after the morning observation at 7 o'clock. There is not so much discomfort in living in the mountains as the record would indicate.

In considering the climate of Idaho Springs, it is important to note a peculiarity in the environment of the place. The town lies nearly in the centre of a loop, open toward the east, made by a considerable curve of the main range of the Rocky Mountain chain. There is a certain protection from this lofty ridge, though it be twenty miles away, in that many of the strong winds which sweep over the mountains, the southerly and northerly more especially, are deflected to one side or prevented from descending to the valley. Mr. Barber, the observer there, has noted this effect. He has often seen that at the same time the upper clouds would be passing rapidly to the north or south, the moving of the foliage on the mountains would indicate another direction of the wind, while down in the town a light breeze would be blowing in still another direction either east or west—*i. e.*, in the direction of the valley. There is no doubt that the mountains surrounding Idaho Springs have a decided influence in tempering the winds and furnishing a certain stillness of atmosphere which is desirable in very cold weather.

A good way to understand the climate of a given locality is to divide its consideration under the heads of the seasons. The winter and summer variations are thus emphasized and one gets a good general idea of the whole year.

Winter.—December is ushered in by some delightfully pleasant and bracing weather. It is not uncommon to see the uniformly sunny autumns in Colorado, with gentle breezes and very little rains, extended over into winter, even into January, after the reports of storms, blizzards, and snow have been received from different parts of the East. The average records for two winters at Idaho Springs give, on the basis already explained, winter mean temperature, 29° F. 7 A.M., 24°; 2 P.M., 39°, and 9 P.M., 26°, with a mean of daily maximum 42°, and of minimum 18°. The precipitation is less than two inches of melted snow, notwithstanding there is an average of about twenty days upon which snow falls. Many of these storms are very light or transient, the sun coming out and shining a half day or more thereafter. The relative humidity of the atmosphere for this season is about 50 per cent.

In December the wind blows at times, but not with great force, and the west wind is apt to prevail in the morning till nine o'clock, when the direction is changed, and the east wind blows very gently till 3 P.M., when the calm of evening comes on. It would be interesting to make comparisons between the winter weather at Idaho Springs and that at Maloja, in the Upper Engadine, where some invalids pass the winter. The difficulty is, the records at hand of the Swiss resort are only for day temperatures—9 A.M., noon, and 3 P.M.—and no exact comparison is possible with our 7 A.M., 2 and 9 P.M. observations. Moreover, even with this advantage for the Maloja Station, the Colorado resort gives higher temperatures for all the averages given as well as for most of the maximum and minimum data recorded. Yet the Maloja is only 6000 feet above sea level, while Idaho Springs is 1500 feet higher.

[1] Read before the American Climatological Association, June 25, 1889.

One finds an explanation of this difference in temperature and rigor of climate in the more northern latitude and greater exposure to sea influences of Maloja, where the limit of tree growth—"timber line"—is at or below the elevation of 8000 feet, while in the Colorado resort, "timber line" is yet 3500 feet higher up, or 11,000 feet above sea level. The writer suggests that it might be as well to reckon both down from "timber line" and up from sea level, when determining the fitness of a given high altitude resort for invalids. From the foregoing it would appear that Idaho Springs, though higher in fact than Maloja, yet is not as elevated so far as the sensations of the individual are concerned. Surely those conditions of climate which limit vegetation, even the growth of the hardiest plants, for instance, scrub oak, the quaking aspen, and the mountain pine or spruce, which hug the mountain sides as though they were afraid to venture far into the surrounding atmosphere, must have an analogous influence upon the human organization. This, and other conditions pertaining to the latitude and the inland protection of the Rocky Mountain region from the influence of the ocean, lead the critic to estimate that six thousand feet elevation in Switzerland is equivalent to nearly eight thousand in central Colorado.

Spring.—It is difficult to find a place where spring is the pleasantest part of the year. In the temperate zone it is usually the breaking-up time—a season akin to the annual house-cleaning, which everybody dislikes. In the mountains the winds are fickle and uncertain, the snows are frequent, though very light, the daily variations of temperature considerable, yet little felt, and though it is often cloudy, there is a large preponderance of sunshine; in fact, all the conditions of the weather betoken a variable and elastic state of barometric pressure, such as might be expected in the attenuated atmosphere of the mountains. It has only lately been recognized that there is benefit and not injury in these frequent electric and barometric changes which are common attributes of the most stimulating and tonic extremes of climate, viz.: sea and mountain air.

The purification of the atmosphere and the oft-repeated renewal of the tonic and electrical conditions are processes constantly impressed upon the mind of the inquirer into high altitude effects, whether he explains it on the theory that the mountains are always giving off the electric force engendered nearer the centre of the earth, or whether he sees in the positive electric state of the dry air the facility in the mountains for an easy interchange between this and the negative electric state of the ground.

Notwithstanding this element of change at Idaho Springs, there are interspersed in the weather records for spring, continuous days and even weeks of sunny beautiful weather, when the day temperature of the air, the freedom from dust or any impurities in the atmosphere, and the little or no snow on the ground to impede mountain climbing, are all that could be desired.

In spring, while rain or snow at Idaho Springs falls on thirty-five days, there are about thirty clear and forty fair days, and the temperature no longer reaches zero—in fact, even during winter it has not averaged so low four times a year for three years. The total cloudiness and precipitation are about the same as for winter, though less than for the summer season. The average temperature for this season is about the average for the whole year, 45° F., made up of the three observations—7 A.M., 39°; 2 P.M., 56°; 9 P.M., 42.2°. The mean of maximum temperature is 59°, and of minimum, 33° F.

This is the time of year when many invalids, who are suited to a higher elevation than Denver, may early seek the greater benefit to be expected from an additional height. It is sometimes better for them not to remain at a level to which they have become fully acclimated and where the good results already enjoyed are in danger of being neutralized by the heat of the approaching summer.

Summer.—The mountains of Colorado are resorted to by many tourists during the summer time. There are not only the invalids from the plains, who have been sojourning in the State, but the newcomers—"tenderfeet"—from the East, together with many inhabitants of Denver and other towns seeking a whiff of mountain air and to enjoy a rest among the hills. A vacation "in the Rockies" with cool nights and bright sunny days will re-invigorate them for another year's work. It seems to the writer that there is a difference between winter and summer, so far as the sensations of a high climate are concerned, that is equivalent to a difference in elevation above sea level of about 1500 feet—that is, 6000 feet in winter are equivalent to 7500 in summer.

The lower temperature; the drier atmosphere, as to actual weight of vapor in the air, and the more invigorating or electric condition (all of which elevation insures), are also, to a certain extent, the accompaniments of the winter season. Therefore, in Colorado, and happily in contra-distinction to the necessities of the climate on the Continent of Europe, the invalid can go up higher instead of down lower when warm weather commences, and thus obtain the cooler, drier, and more stimulating climate he needs. The facilities for camping out in the summer time are unsurpassed by any country, because of the uniform dryness of the air, the porous, sandy condition of the soil, the natural drainage of all sections, and the comparative freedom from the annoyance of insects.

The average for three summers, 1886 to 1888,

gives a mean summer temperature of 62.5° F. at Idaho Springs, the mean at the three hours of observation being, 7 A.M., 59°; 2 P.M., 74°; and 9 P.M., 59°. The mean of the maximum is 77.2°, and of the minimum temperature 42.6°. The precipitation is about seven inches of rainfall, and the cloudiness about forty and the relative humidity about fifty per cent. The showers of summer are more apt to be genuine rain-storms, which happily come and go quickly, allay the dust and are prevented from contributing much moisture to the air because of the quick drainage and the character of the soil.

Autumn.—The fall is the most attractive of all the seasons. The unprecedented number of bright sunny days; the changing foliage with beautiful autumn tints; the absence of dense clouds; the continuance of the unsurpassed sunsets and sunrises, together with the cool nights, when sleep is never more refreshing than after a healthful and invigorating hunt or ramble among the hills—all are but parts of an experience which will never be forgotten by the tourist or invalid who spends an autumn in the Rocky Mountains.

Unfortunately, however, the travelling public, and especially the invalid portion, are a restless set of mortals. No sooner have the autumnal tints begun to appear, or the frosted leaves to fall, than the demands of business call away the tourist, homesickness, or a restless fear of "catching cold," seizes the invalid, and, like a flock of sheep, they all go together and hotels are deserted. Invalids will return to indoor and confining occupations, which they had better have never begun; while others, after loafing about the town till colder weather appears, will catch the "California fever," only to return to Colorado in another year, regretting they had not followed the doctor's advice. Some, however, will systematically continue to live an out-of-door life, which in this climate their experience has proved to be capable of arresting or eradicating their disease.

The population of Colorado has been largely augmented by this class of recuperated invalids. Consumptive patients, as a rule, who have received benefit in the mountains, come down to the plains too soon in the autumn. It would be much better for some of them did they consider their summer's improvement as a stepping-stone or preparation for still greater advances on the road to health.

The records of three autumns, '86 to '88, give a mean autumn temperature of 44° F., taken from the three daily averages, 7 A.M., 38°; 2 P.M., 56°; and 9 P.M., 41°—the means of the daily maximum temperature being 60.4°, and of minimum 33.4°.

The rain falls on only fifteen days, and only four or five days are put down as cloudy, the rest of them being fair or clear. The cloudiness is noted as about thirty-five per cent. of the time, and the average precipitation is between one and a half and two inches of rainfall during the whole season. This is a very good showing, and these are probably as accurate records as can be obtained from the average voluntary observer.

A NEW POSITION FOR FACILITATING THE OPERATION FOR VESICO-VAGINAL FISTULA, AND OTHER OPERATIONS ON THE UTERUS AND VAGINA.

BY J. F. HEUSTIS, A.M., M.D.,
PROFESSOR OF SURGERY IN THE MEDICAL COLLEGE OF ALABAMA.

THE idea of Sims, of utilizing atmospheric pressure to dilate the vagina, is "at the bottom" of all the positions for bringing the parts clearly into view and easily accessible. His position is the one commonly used in connection with his speculum, and the traction of the perineum upward with a speculum of variable width, form, and adjustability completes the necessary opening and stretching of the vagina. Bozeman makes the atmospheric dilatation more efficient by holding the patient in a kneeling position by a special apparatus of his devising.

Having had great difficulty in keeping strong patients in Sims's position, I have devised what appears to me to be the best and simplest method yet. I was driven to it by an operation for vesico-vaginal fistula on a woman of great size and voluminous vagina. It seemed impossible to complete the operation on account of her unruliness, as well as the bad character and situation of the fistula. Knowing that the successful dilatation and patulousness of the vagina were dependent on atmospheric pressure, and that to obtain this the belly should have room to hang clear of the table (so that the gravitation of the bowels would create a vacuum), I had a thick, *hard* pillow shoved under the upper part of her thighs, reaching to the pubes, but not to the pendulous part of the belly, the woman being prone, with her legs stretched out straight. It answered the purpose perfectly. The vagina was so widely open and expanded that the operation was done with the greatest ease. All the advantages of Bozeman's apparatus were obtained, and all the difficulties of Sims's position done away with.

On another occasion, not having the right sort of pillow at hand, I wrapped a large family Bible in a sheet and shoved it under the pubes and upper part of the thighs, testing the elevation of the belly by sliding my hand beneath it. As it is generally easy to get a big Bible or Webster's unabridged dictionary, or a hard pillow, it brings the accomplishment of our purpose within easy reach.

The prone position, with the limbs stretched out, is much easier maintained than the constrained one of Sims or the position on the knees of Bozeman, which, of course, cannot be kept up with the patient under chloroform without his apparatus.

Simple as this procedure is, I have seen no mention of it anywhere.

MEDICAL PROGRESS.

The Value of Caffeine in Adynamic Conditions.—In spite of the continued endeavors of DR. HUCHARD, of Paris, to demonstrate to the medical profession the value, and simultaneously the harmlessness, of large doses of caffeine, still there seems to be a prejudice against the drug and a ruling idea that its free use is likely to produce unpleasant cardiac symptoms. New remedies, of doubtful efficacy, that are springing up daily, find no lack of advocates, whilst many comparatively older drugs do not receive the attention that their curative properties warrant. This is Huchard's complaint, as he once more brings to the notice of the profession the value of large and repeated doses of caffeine in all adynamic conditions. As an example of its efficiency, Huchard, in the *Therap. Monatsheft* for August, cites the case of a gouty man who was suffering from a right-sided pneumonia, and who, twelve days later, developed an inflammation of the left lung. The patient fell into a condition of extreme adynamia, and collapsed. During the following thirty days, Huchard gave this patient 95 hypodermatic injections of caffeine, of 4 grains each, 51 injections of ether, and 19 of trinitrin. The result of the treatment was satisfactory beyond all expectations. The author quotes five other cases in which the value, as well as the harmlessness, of the drug in large doses is clearly demonstrated. He employed it in four other cases of pneumonia; in such instances, "the disease is in the lungs, but the danger in the heart." Huchard does not hesitate to employ subcutaneous doses as high as 31 to 48 grains. The reported efficacy of daily doses of 3 to 5 grains is entirely illusionary.

Huchard's experiments upon animals proved that the drug acted upon the central nervous system before it influenced the heart. There is, therefore, a marked difference between the action of digitalis and caffeine. Digitalis affects primarily the heart, caffeine the nervous system.

In conclusion, the author asserts:

1. That the great value of large doses of caffeine, given subcutaneously, in all adynamic conditions is unquestionable.

2. That large doses of caffeine are entirely harmless.

Toothache Drops.—The *Therap. Monatsheft* for August gives the following:

℞.—Extract of opium Camphor trit. Balsam of Peru	. .	āā 8 grains.
Mastic		15 grains.
Chloroform		f℥iij.—M.

Soak a pellet of cotton in this mixture and place it in the cavity of the tooth.

Asthma and the Uterine System.—DR. PEYER has recently written in the *Berliner Klinik*, Part 9, 1889, on an affection which he terms sexual asthma. He maintained that asthma was always neurotic, and that in different subjects asthmatic convulsions were brought on by the influence of different physical functions. In two young married women, coitus caused violent attacks of asthmatic sneezing. In another case the patient suffered from uterine fibroid, with severe asthma, which disappeared after the removal of the tumor. A patient was subject to violent asthmatic fits; on her becoming pregnant for the first time, the asthma was completely cured. In a similar case of asthma the patient suffered from chronic metritis. When the uterine affection was cured, the asthmatic complication disappeared. In all Dr. Peyer's cases the patients were more or less hysterical, and in two there was a distinct family history of neurosis. The physician must be careful now to distinguish between the possible coincidence of true asthma and disease of the sexual functions and the alleged form where the former is an effect of the latter. In the case of coincidence it is perfectly easy to understand that any aggravation of uterine or ovarian disease and any irritation of the sexual functions might aggravate the asthma. The other condition is less easy to understand, and very hard to prove in a scientific manner.—*British Med. Journ.*, August 31, 1889.

The Ptomaine of Rabies.—Recently, DR. W. ANREP reported to the Medical Society of St. Petersburg the results of numerous experiments with rabies. He claims to have discovered the ptomaine causing this disease. The results of his experiments, as stated in the *Centralblatt f. Bakt. und Parasitk.*, of July 19th, are as follows: From the brains of rabbits which had died with hydrophobia he extracted a substance of an alkaloidal appearance, which proved to be a most poisonous ptomaine. One thousand brains contained only three-quarters of a grain of the poison. Both the pure ptomaine as well as the salts thereof crystallize in water. Its chemical composition is as yet undetermined. Minute doses (about $\frac{1}{1000}$ to $\frac{1}{750}$ of a grain), given to animals, produce a rise of temperature, restlessness, quickened respiration, and palpitation. Doses of $\frac{1}{600}$ to about $\frac{1}{300}$ of a grain produce, in addition to the above-mentioned symptoms, difficulty in breathing, slight convulsions, slight heart failure, and general weakness. Larger doses, $\frac{1}{250}$ to $\frac{1}{150}$ of a grain, produce sinking of temperature, paresis of the extremities, flow of saliva, and death from asphyxia. In other words, the ptomaine can produce all the symptoms of rabies.

A Minimum Cauterizer. — The finest cautery, either Paquelin's or an electric one, causes an eschar three or four times its diameter, and though this is not of much consequence when diseases which themselves leave a scar are being dealt with, it is otherwise when a rosacea or a capillary nævus is so treated. TAENZER, in the *Monatsh. f. Prakt. Derm.*, has discovered a plan by which a cautery causing a much smaller eschar can be made, and has designed one of the following principles: A finely pointed copper needle, set in an isolated holder, is surrounded by a platinum spiral, which does not quite come in contact with the needle, and does not extend to its point. When the spiral is connected with both poles of the battery it becomes red-hot, but it does not raise the temperature of the included needle so high. The copper needle does not become red-hot, merely very warm. In addition, the diameter of the included needle is much less than in any other form of electric cautery. These two

combined factors, the small diameter of the cautery and the low temperature, render it possible to produce such a small eschar, that it is less than the head of the smallest pin, and the scar which remains is invisible without a lens. With this instrument one can fearlessly cauterize wide areas, as, for example, port-wine marks on the face; but care must be taken not to crowd the eschars too closely together. The needle must, however, be brought to the proper heat before cauterization is begun, and this can best be estimated if the needle can be easily withdrawn from the skin. If the needle is not hot enough, it can only be extracted with pain and difficulty.

Cultures from Vaginal Secretions.—DR. E. LEGRAIN, in the *Centralbl. f. Bakt. und Parasitk.*, of July 19th, describes several cultures which he has obtained from normal vaginal secretions. The cells themselves are round, and have a diameter of from 6 to 8 μ. In old cultures spindle-shaped microörganisms are found, which reach a length of 15 μ. Cultures in gelatine, after one week's time, bear a great resemblance to those of anthrax; later, however, these cultures lose their characteristic appearance. At a temperature of 95° or 97° the cultures grow with great rapidity. In a week large cultures will be formed on agar-agar; these are white, moist, and of a sticky consistency; after three weeks they cease to grow.

Salve for Infantile Eczema.—DELAPERT gives the following in the *Revue de Thér. Méd.-chirurg.* of September 1st:

℞.—Boric acid . . . . . ℥jss.
Vaseline . . . . . ℥j.
Balsam of Peru . . . . grs. viij.—M.

Sig.—Apply the ointment frequently to all the affected parts.

Antiseptic Properties in Human Saliva.—From a series of experiments with the saliva of human adults, DR. FLORADIN has found that the sulpho-cyanide of potash, which is always present, has decided antiseptic properties.—*Prager med. Wochenschrift*, August 21, 1889.

Hysterectomy for Fibroids.—PROFESSOR ALBERT has published, *Wiener med. Wochenschrift*, ii., 1889, a paper on ten successful cases of abdominal section for myoma of the uterus. In all, the extraperitoneal method of treating the stump was adopted. The elastic ligature was used in order to prevent hemorrhage during the enucleation of the fibroid and the amputation of the uterus, the stump being fixed with pins. In one case an abscess in Douglas's pouch was laid open during the operation. The abscess was drained through the posterior vaginal fornix, the tube being removed on the fourteenth day. In another Professor Albert found a pancreatic cyst in close proximity to the uterine myoma, which was very large, and removed both. This remarkable case will, the author informed his readers, be published in full. In one (and apparently in only one) of the ten cases a myoma had to be shelled out of the hyoid ligament. The posterior layer of the ligament was sewn to the abdominal incision, and the cavity left between the layers was stuffed with iodoform gauze. Professor Albert rejected the use of sponges for cleaning the peritoneum, and attributed his success in no small degree to this new departure.—*British Med. Journ.*, August 31, 1889.

A New Antidote for Morphine.—From the result of numerous experiments, DR. BÓKAI has become convinced that pikrotoxin is the most rational antidote for morphine. The action of morphine and pikrotoxin upon the respiratory centre is antagonistic, as morphine causes paralysis of the respiration, and pikrotoxin prevents this. Furthermore, pikrotoxin acts powerfully upon the vaso-contractive centres of the medulla oblongata, and in this way can rapidly decrease the abnormal blood-pressure caused by morphine. The action of the two drugs upon the cerebrum is also antagonistic. Bókai suggests the possible utility of the drug in chloroform asphyxia.—*Centralbl. f. klin. Med.*, August 17, 1889.

A Temperature of 112.8° F. followed by Recovery.—A case of fever is reported by DR. CARL LORENTZEN, in the *Centralbl. f. klin. Med.*, of August 17th, in which, although the temperature reached the astounding height of nearly 113° F., an ultimate recovery of the patient took place. We subjoin a brief history of the case:

The patient was a woman, aged twenty. As a child she had been "nervous," but there were no symptoms of hysteria. One night, after retiring, she suddenly coughed up half a tumblerful of blood. Inspiration became impossible; her face grew rapidly cyanotic. She threw herself back, and in a few moments the attack ended, and free inspiration was possible. Shortly after this she had similar attacks, which continued all night in spite of injections of morphine and ether, and cold douches, etc. During the long attacks she lost consciousness, and cyanosis was extreme. She complained of pain in the chest during deep inspirations, and this symptom always preceded an attack. Although carefully examined, no pathological conditions of the organs of respiration and digestion were found. The next day the attacks set in again, but were not so frequent. The urine, although frequently examined, was always found normal. For the next two months she had slight hemoptysis at intervals, and frequently was troubled by retention of the urine, which necessitated catheterization. Menstruation was normal. On the first of January, hemoptysis becoming more frequent, she kept her bed. During the early part of the month her temperature varied from 103° to 105° F.; patient was very weak, had chills, but did not perspire; loss of appetite, nausea, vomiting, constipation, and retention were among the symptoms complained of. During the night of the ninth the temperature rose to 112.8° F. in the rectum and 112.5° in the axilla. The patient was slightly delirious, but could be roused. Pulse 144 and full. Respirations 24 and regular. Difficulty in breathing began, but the attack was warded off by the inhalation of a few drops of chloroform. From then to the twelfth of the month the temperature remained very high, ranging from 104° to 107° F. After that, recovery was steady, and in a few months was complete. She is now enjoying excellent health.

Diagnosis was, of course, most difficult, and Lorentzen can only explain the erratic symptoms and temperature by putting them down to a hysterical origin.

Diplococcus Pneumoniæ the Cause of Peritonitis.—In three cases of peritonitis DR. WEICHSELBAUM has found the diplococcus of pneumonia unaccompanied by any other microörganism. In the one case peritonitis and acute

pneumonia existed simultaneously; in the other, pleurisy of both sides developed later; but in the third the peritonitis was unquestionably primary. Until now the streptococcus pyogenes has been regarded as the cause of peritonitis.—*Centralbl. für Chirurg.*, August 17, 1889.

Treatment of Cancer of the Rectum.—MR. T. R. JESSOP, in his address before the Section of Surgery of the British Medical Association, reported in the *British Medical Journal* of August 24th, in speaking of the treatment of cancer of the upper movable part of the rectum, said:

"If, then, we are satisfied that we have to deal with a case of cancer situated in the upper movable part of the rectum, knowing that complete obstruction may of a certainty be looked for, we shall probably all agree that it is desirable to make an artificial anus in the colon above as soon at least as the first symptoms of impending blockage appear, and in time to anticipate those further changes upon which the mortality of colotomy so much depends. And I will here state my opinion that in these circumstances the ordinary left lumbar colotomy is to be preferred, not only because of the facility with which the distended bowel is reached, but chiefly because the opening is made at a sufficient distance from the disease to insure its being found in a healthy state, free alike from cancerous infiltration and from those ulcerative changes which are apt to occur on the distal side of a strictured canal. That an early operation is called for is abundantly shown by a reference to the mortality in the cases just mentioned. Of the fifteen operated on for complete obstruction, five died within the first week, two within three months, and the remaining eight lived an average of rather more than twelve months, including one who survived the operation twenty-two months. On the other hand, of the nine operated on when no symptoms of obstruction were present, the earliest death did not take place for upward of two months, and the average of life throughout was a little over eleven months. And, again, reviewing a larger series, I find that out of fifty-four cases of colotomy taken from both my hospital and private note-book, performed for the relief of distress only, and not for obstruction, three only died during the first month, and in each of these there were some special circumstances, such as advanced age or great emaciation, to account for the early death. It is not in cases of complete obstruction or of threatened obstruction that any difficulty arises in the course to be pursued. When death is imminent and other means have failed to bring about relief, an opening somewhere and of some kind in the bowel for the exit of the pent-up excreta is obviously called for; and, as we have seen, the earlier that opening is made the more certainly will a lasting relief be obtained. And, following out the result of my observations, I would say that, given a diagnosis of cancer high up in the rectum—in the earlier stages, it is true, by no means always an easy matter—the duty of the surgeon would seem clear, namely, to recommend without delay the formation of an artificial anus."

Two Formulæ for Tooth-powder.—The following formulæ for acid and alkaline tooth-powders are given by DESCHAMPS in the *Revue de Thér. Méd.-chirurg.*, of September 1st:

Acid Tooth-powder.

℞.—Venetian talc	℥ jv.
Cream of tartar	℥ j.
Carmine	grs. v.
Essence of menthol	gtt. xv.—M.

Alkaline Tooth-powder.

℞.—Venetian talc	℥ jv.
Bicarbonate of soda	℥ j.
Carmine	grs. v.
Essence of menthol	gtt. xv.—M.

Creasote in Phthisis and Pulmonary Tuberculosis.—PROFESSOR SOMMERBRODT, says the *Medical Press* of August 21st, is an enthusiastic believer in the special virtues of creasote in phthisis and pulmonary tuberculosis. After an extensive use of the drug he gives us statistics of 5000 cases he has treated in hospital. He claims for it the power of improving the appetite, limiting the secretions, and diminishing the irritable cough. Its primary virtue, however, is its anti-bacterian property, which checks the progress of the baneful disorder. He supports his belief by pointing to Guttman's bacterian experiments with the tubercular bacilli, which he cultivated in glycerine and destroyed with a 1:4000 solution of creasote. From this experiment Guttman himself reasoned that, if he could get this quantity into the circulation without injury to the organism, he might be able to arrest the progress of the bacilli; but when he considered that a man of 60 kilos (160 pounds) contained 4615 grammes of blood (9 pounds) that would mean upward of one gramme of creasote to be present in the circulation before any good effect could be expected.

From this data Professor Sommerbrodt postulates his treatment, and has capsules made, each containing 0.05 gramme (0.77 grain). Three of these capsules are given on the first day, four the second day, five the third day, and so on till twenty-one—or twenty-nine, which he gave in three cases—are given, which would represent 1.35 grammes (21 grains) of the drug taken daily. This exactly completes Guttman's hypothesis of creasote, and Sommerbrodt believes that the facts of his results are perfectly consonant with Guttman's presumption. He points to a case sent him last year by a military surgeon. The patient was an officer in the army with marked tuberculosis, dulness over the fossa supra-spinata dextra, rhonchi, emaciation, increasing cough, with spit in which the bacilli and elastic tissue were to be found in great quantities. A year before this he had pleuritis sicca dextra.

On September 1st the creasote treatment commenced, and by September 18th he was using twenty capsules a day. On September 29th the morning sputa had very few bacilli, with a few fibres of elastic tissue. On November 1st he returned to duty, general health improved, dulness disappeared, and morning cough left him in a short time. During the whole winter he attended to his duty in the midst of snow and rain, during which period he gained twenty pounds in weight. By the month of April this year every sign of tuberculosis had disappeared, and perfect health seems now to be established.

From September 1st to June 1st he had used 5400 capsules, representing 270 grammes of creasote (nearly 7 ounces), and 1080 grammes of balsam of Tolu (35 ounces) with which it was combined. He assures us that he has treated many other cases in the same way.

Although actual experiments with animals do not confirm this opinion, Sommerbrodt is convinced that creasote does more than improve the digestion, according to Klemperer, or reduce the secretions, as Cornet believes. Sommerbrodt proposes that Koch should examine the blood serum of a patient after a month's use of gramme doses, and he thinks he will find that all bacilli have disappeared. He advises the creasote, which may be taken either in the form of capsule, tincture, or wine, to be administered immediately after food.

Treatment of Exophthalmic Goitre with Cannabin.—VALIÉRE in the *Revue de Thér. Méd.-chirurg.* of September 1st, gives the following formulæ for the treatment of exophthalmic goitre:

I. ℞.—Cannabin . . . . grs. iij.
Lactose . . . . . q. s.—M.

Make into five pills; to be taken in twenty-four hours.

II. ℞.—Cannabin . . . . grs. iij.
Distilled water . . . ℥ iij.
Syrup of orange flowers . . ℥ j.—M.

Sig.—To be taken in twenty-four hours, in teaspoonful doses.

Decomposition of Chloroform by Gaslight.—Much has been said upon this subject of late, and the opinion of the danger of the administration of chloroform by gaslight has been almost universally substantiated. PROF. BOSSHARD has added additional confirmation to the conclusion already reached by experience, by his careful chemical analysis of the changes undergone by chloroform when allowed to evaporate in the proximity of a gaslight. The following substances are formed:

1. Carbonic oxydichloride (phosgene gas).
2. Muriatic acid gas.
3. Free chlorine.

The harmful action of the two last-named gases is already well known, but the toxicity of phosgene gas is still uncertain.

DR. STOBWASSER, in Berlin, has recently conducted a series of toxicological experiments with rabbits and guinea-pigs. He put them into a glass case provided with two doors for ventilation, and introduced a flat dish containing chloroform, and near it a gas-jet.

When only one burner was used, and a small flame, the animal quickly showed symptoms of severe dyspnœa and labored respiration. When two or three burners were used these symptoms were greatly intensified, and the animals invariably died soon after the completion of the experiment, and frequently during its course.

The conclusions deduced by Stobwasser from these experiments are obvious. The danger of administration of chloroform by gaslight is, therefore, unquestionable. True, this may be in a measure mitigated if thorough and ample ventilation is secured, but still Stobwasser looks forward to the introduction of the electric light for surgical operations by night.

The Causes of Recurrence of Mammary Cancer.—The advances of modern surgery in the field of operations for carcinoma has, of late, been most extensive. The thoroughness with which such operations are now conducted, when not only the entire growth, but also the neighboring structures and lymphatics are also removed, differs greatly from the old method of operating. Foremost among the recent workers in this field have been Thiersch and Volkmann. All the same, in spite of many brilliant operators and numerous learned essayists, the results of extirpation of the mamma for carcinoma are most unsatisfactory. DR. HEIDENHEIM, of Berlin, has recently been investigating the causes of the almost inevitable recurrence of mammary carcinoma. His researches, as quoted in the *Fortschritte der Medicin* of August 15th, have been most fruitful.

In eighteen cases of cancer he subjected the extirpated gland to a most careful microscopical examination, and in twelve cases found cancerous elements at the base of the growth and prognosticated a recurrence of the disease. His prognosis was confirmed. In the remaining six cases the base of the extirpated gland was found to be healthy, and here the favorable prognosis advanced by Heidenheim has also been substantiated.

Heidenheim formulates the results of his investigations in the following conclusions:

1. The pectoral fascia is very thin and its limits very uncertain, so that it is impossible to divide it from the muscle without leaving portions of the tissue adherent. This is especially the case in corpulent females.

2. In thin women the mammary gland is distinct, but in stout women small portions of the same are adherent to the neighboring fascia and muscle, and therefore it is very probable that, after amputation, small portions of the gland will remain adherent.

3. It may be almost positively concluded that if a mammary gland contains even a small cancerous nodule it is diseased throughout its entire extent. The epithelial cells of the acini and the connective tissue become extensively infected. The lymphatics of the mamma carry these epithelial cells to some distance. Possibly one cause of recurrence of the disease is due to the acini which remain after the extirpation.

4. In conjunction with bloodvessels, lymphatic ducts stretch from the glands deeply into the retro-mammary fat. In two-thirds of the cases examined cancerous metastasiæ were found in these lymphatic ducts. Through this channel the disease can go forward until it reaches the fascia.

5. The pectoralis major is usually healthy when the tumor is in no way attached to it. It is, however, diseased when cancerous nodules are found adherent to its fascia, and also when the body of the tumor is attached to it. Probably the disease is introduced into the muscle through the lymphatic ducts.

6. Possibly, also, the contraction of the muscle, through movement, as well as the lymphatic stream, aid in carrying the infection to the surrounding tissues. A muscle infected with cancer seems to be diseased in its entire extent.

Guided by the above conclusions, Heidenheim advocates that, in cases of mammary carcinoma where the tumor is perfectly free and movable, the entire growth with surrounding tissues, and also the superficial portion of the muscle, should be removed; when, however, the growth is adherent to the pectoralis major, total extirpation of that muscle is necessary.

These important and well-founded suggestions have been most attentively considered by German surgeons. It is, indeed, to be wished for that the result of this operation should become more certain and more hopeful.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, SEPTEMBER 21, 1889.

ALBUMINURIA WITH REFERENCE TO PROGNOSIS AND LIFE INSURANCE.

A VERY interesting discussion on this subject, rendered especially important by reason of the eminence of those who participated in it, took place at the recent meeting of the British Medical Association, at Leeds. It followed the reading of an introductory paper by DR. F. W. PAVY, and, with the exception of Drs. Grainger Stewart, Roberts, and Dickinson, few English physicians whose names are associated with renal disease failed to take part. Much of interest was said collateral to that of the title, but we shall confine ourselves strictly to matter pertaining to it.

Dr. Pavy divided the cases of albuminuria intended to be covered by the discussion into three groups: (1) Cases in which traces only of albumin are present—meaning by traces quantities which require careful testing for their recognition, but by tests free from fallacy; (2) cases in which a notable amount of albumin exists and is always present; (3) cases in which a notable amount of albumin is found at one period of the twenty-four hours, and none at another—or, in other words, cases of cyclic character.

In those of the first group, *with everything else bearing upon the point pronounced to be satisfactory after a full and careful investigation of the case*, Dr. Pavy would not consider the prospects of life insurance invalidated. The granular kidney being the form of renal disease especially associated with small amounts of albumin, conditions belonging to this affection are to be particularly sought for, viz., increased quantity of urine, low specific gravity, and morbid changes in the cardio-vascular system.

Of the second group it would only be in a case that had been under distinct observation for a considerable time without anything wrong being developed, that he would venture to look favorably upon the prospects, and even then he should consider that a decidedly more than usual risk existed.

Of the third group—the cyclic albuminuria—the distinguishing feature is, that without evidence from other sources of the existence or *pre*-existence of renal disease, in the ordinary course of daily life albumin is at one period of the day present and at another absent, and that this recurs day after day in exactly the same order. Thus, on rising in the morning, there is no albumin; in an hour or two it appears, increasing for a time, and then as the day advances declines, and generally entirely disappears before bedtime. This repeats itself the next day, and so on. With respect to these cases, Dr. Pavy feels warranted in saying that if, on a sufficiently full and careful inquiry, a case is found to fall in this category, the risk may be favorably regarded. He thinks it not unreasonable, however, that an additional premium should be asked to meet the possible contingencies which may arise.

Those who are familiar with the writings of DR. GEORGE JOHNSON given out at various times on the subject of albuminuria, will be prepared to hear that he does not agree with Dr. Pavy. He says: "No medical officer, I suppose, would advise that a proposed assurer with a decided trace of albumin in the urine should be accepted at the ordinary rate of premium. Such a condition, even in a careful and prudent man, must involve some extra risk, and no office can insure care and prudence. Whether an albuminuric should be accepted on any terms can be determined only by a careful inquiry into the particular history of each case."

Dr. Johnson is very emphatic in insisting that all urines containing albumins, however small in amount and even occasionally intermittent, are pathological, which we do not think any one will dispute. He objects even to the term "functional" albuminuria, and says that in almost every instance these cases of albuminuria may, by a careful inquiry, be traced back to some recognized exciting cause, in which we are less inclined to agree with him.

DR. R. MAGUIRE thinks that when albumin is present at the time of the examination for insurance, the life should be rejected, or, if accepted at all,

should be accepted at an increased premium. DR. P. H. PYE-SMITH also regards "functional" albuminuria as really "pathological for the time being," and would defer the applications for assurance rather than attempt to determine what is often an insoluble question. DR. W. T. GAIRDNER could not find a more just or accurate expression for his opinion than to say that serum albumin, when present in the urine even casually, must be regarded as a danger signal. As for the amount of danger implied in the fact in particular cases, he was neither pessimistic nor optimistic. He, in a general way, accepted Dr. Pavy's conclusions, both as to the significance of the fact and the other circumstances to be taken into account in forming a prognosis. He thought, however, that even in a case otherwise acceptable, judgment must be postponed for a period varying, according to circumstances, from weeks to months.

DR. RABAGLIATI made a good point with regard to the specific gravity of the urine, saying that above 1020 it suggested lithæmic nephritis; if below 1010 it suggested further advance of the disease. On the whole, he could not support those who were disposed to take a favorable view of the cases in which even a trace of albumin was present.

DR. C. R. DRYSDALE thought that in temporary albuminuria delay is advisable before coming to a definite conclusion, while DR. R. SAUNDBY is a firm believer in the innocent character of albuminuria in certain cases, and would, therefore, gladly see some change in the present practice of the majority of insurance companies if it could be brought about with due regard to their interests.

DR. W. J. TYSON thought that the popular knowledge concerning the presence of albumin is causing a needless amount of anxiety, and made the happy suggestion that the Collective Investigation Committee take up the subject of prognosis in these cases of permanent, but apparently harmless, albuminuria.

DR. J. E. EDDISON, of Leeds, thought that every case of albuminuria referred for report as to life insurance should either be refused or deferred six months or a year, and if the albumin persisted, should be rejected, no matter how healthy the applicant appeared in other respects.

We regard the contribution of DR. CRANSTOUN CHARLES as one of the most valuable the discussion received in the way of furnishing tangible data whence conclusions dare be drawn. He reported the results of some observations upon apparently healthy students and others, similar to those made by Grainger Stewart and published in his new book on albuminuria a year ago. Out of 250 of the former, 34, or 13.4 per cent., presented albumin in the mid-day urine, and of 72 pupils in a training-college albumin was present in the after-dinner urine of 24, or 33⅓ per cent., while in half of these peptones were also present. Out of 100 candidates from the country there was albumin in the morning urine of 30.

It will be seen that there was not as much unanimity of opinion upon this important subject as could be desired. Dr. Pavy and Dr. Saundby alone are clearly of the opinion that albuminuria should not be an unconditional obstacle to life insurance. In this they are partially sustained by Drs. Gairdner and Drysdale, while Drs. Johnson, Maguire, Pye-Smith, Rabagliati, and Eddison would evidently consider it a hindrance scarcely, if at all, surmountable. Much discussion about a term is scarcely profitable. As intimated, we hardly think that any one will claim that an albuminuria is to be regarded as "physiological," or, strictly speaking, even as "functional." But it does not follow from this that a small amount may not be compatible with sound health, as such observations as those of Cranstoun Charles, given above, and of Grainger Stewart, conclusively show. We cannot see that an impartial examination of such statistics as these permits any other conclusion. Of course, such cases must not be confounded with cases of albuminuria due to structural change in the kidney. Hence more than ordinarily close investigation is often needed to distinguish them, but such distinction being made, we cannot see a sufficient reason for altogether rejecting such applications, provided, as Dr. Pavy said, everything else bearing upon the point be pronounced satisfactory after a full and careful investigation of the case.

As intimated, a number of other important facts were brought out in this discussion. Thus Dr. Pavy makes, in passing, the statement that whereas in structural renal disease there is usually present only serum albumin, thrown down by the mineral but not by organic acids, in cyclic albuminuria his experience leads him to believe that it is the rule rather than the exception, that the addition of an organic acid is followed by a precipitate, showing the presence here of two kinds of albumin, one like alkali-

albumin and mucin, precipitated by organic acids, and the other serum albumin.

Dr. Rabagliati had also noted, that out of 3246 deaths in the Scottish Widows' Fund, 255, or 7.8 per cent., were due to "urinary" diseases. Of these, rather more than one-half, or 4.3, were ascribed to "disease of kidneys and nephritis." He had compared this with the deaths among adult males in a mixed population like that of Bradford. There, among 3317 deaths of males above fifteen years of age, only 3.4 per cent. were returned as due to urinary diseases. Without laying too much stress on this, he thought it showed a *prima facie* case for the view that the well-to-do, who applied for life insurance, suffered more from urinary diseases than the ordinary population—mainly because well-to-do people ate and drank too much.

THE Canadian Medical Association held, on the 12th and 13th of last month, a most successful annual meeting at Banff. The meeting was very largely attended, and is said to have been most enjoyable in every way. The United States was represented by Drs. Currie and Whittaker, of Cincinnati; Dr. Baker, of Philadelphia; Drs. Gibney and Bulkley, of New York, and others. Toronto was decided upon as the next place of meeting.

THE First International Congress of Physiologists was opened at Basle, Switzerland, on the 10th inst., and sat for three days.

THE chair of gynecology and obstetrics in the University of Vienna, rendered vacant by Breisky's death, will be filled by PROFESSOR CHROBAK, of Vienna.

The chair of medical pathology and therapeutics at Prague has been filled by PROFESSOR VON JAKSCH, of Graz. Both appointments seem to give general satisfaction.

WE note that PROFESSOR WEIGERT, who has edited the *Fortschritte der Medicin* ever since the death of Dr. Carl Friedländer, its founder, has resigned its editorship.

IT is stated that Mr. Reginald Harrison, of Liverpool, a well-known authority on diseases of the urinary organs, is about to take up his residence in London.

PARIS has indeed had her fill of International Congresses during the past two months, and this year may justly be remembered as "the year of congresses" in that city. Yet all have not been chronicled, for we read in the *Münchener med. Wochenschr.* that even an Anti-vaccination, or, more broadly speaking, an International Anti-inoculation Congress, was held last month. The use of a room in the City Hall of Paris was denied the Congress.

AN institute has been founded in St. Petersburg for the experimental study of infectious diseases and for prophylactic inoculations. The institute is to be under the charge of Professor B. Anrep.

Two cities that have been almost revolutionized in their sanitary conditions are Munich and Memphis. In the former typhoid fever was one of the high factors of the bills of mortality before Pettenkofer instituted his measures of reform, whereas now the fever is so rare that the medical teachers are often at a loss for a case to show to their classes. From being one of the most unhealthful of European cities, Munich has become one of the most salubrious; it is more prosperous, from an influx of strangers who are settling there, and from the increased attendance of students at the University. Memphis is still engaged upon its sanitary reforms, being busy with the introduction of an artesian water supply of admirable quality. Memphis was formerly a notoriously unhealthful town, and suffered greatly from epidemic disease, whereas to-day she has as low a mortality as any city in the country having the same population. In the words of Dr. Conn, "the change that has come over the city in less than ten years seems more like the tales of romance than the mere realization of a scientific and economic truth."

IN Japan there are thirty-one schools of medicine, one of dentistry, and two of veterinary surgery. The university of Tokyo (the Imperial University) has over 1200 students, and an average of 100 medical students graduate yearly. In Tokyo alone there are numerous active medical societies and over twenty hospitals.

THE Second Congress for Tuberculosis will be held in Paris during the latter part of July, 1890. Professor Villemin will act as president. The following questions are to be discussed: 1. The identity of human and bovine tuberculosis, also that of other animals. 2. The bacteriological and morbid associations of tuberculosis. 3. The isolation of

tuberculous subjects. 4. The agents capable of destroying Koch's tubercle bacillus, with a view to the prophylaxis and therapeusis of the disease in man.

WE learn from the *Gazetta degli Ospitali* that the Seventh International Pharmaceutical Congress will be held in Milan during the first part of September, 1890. A committee of arrangements has already been appointed.

THE second Italian Congress for Internal Medicine will be held in Rome from the 15th to the 18th of October of this year. The subjects to be discussed will include malarial infection, the pathology and therapy of nephritis, and gout.

REVIEWS.

A TREATISE ON SURGERY, ITS PRINCIPLES AND PRACTICE. By T. HOLMES, M. A. Cantab., Consulting Surgeon to St. George's Hospital, Member Associé de la Soc. de Chir. de Paris. With 428 illustrations. Fifth edition, edited by T. PICKERING PICK, Surgeon to, and Lecturer on Surgery at St. George's Hospital; Senior Surgeon Victoria Hospital for Children; Member of the Court of Examiners Royal College of Surgeons, England. Pp. 1008. Philadelphia: Lea Brothers & Co., 1889.

HOLMES's Surgery has always been a popular book, and now that a fifth edition has been issued, it will be safe to predict a favorable reception for it. A large number of alterations and additions have been rendered necessary by the steady growth of surgical science, and in the main these additions are judicious and in accordance with the doctrines of the present day.

The chapter on "Diseases of the Eye" has been omitted, both in order to make room for the necessary enlargement of the work, and because it is impossible to do justice to such an important subject in a limited article. Our author is a strong advocate of "antiseptic surgery," but we cannot think that all of his views in regard to this matter are either safe or correct—for instance, it is recommended to wash out the peritoneal cavity with a sublimate solution, "which should not be used of a greater strength than 1 in 4000." This is certainly a dangerous strength to use for this purpose. The spray is only recommended as a purifier of the atmosphere prior to operation, but most surgeons will fail to believe that the "bacteria which may be floating in the air" are destroyed thereby. It is recommended to redress the wound at the end of twenty-four hours, and to allow no antiseptic dressing to remain longer than a week without removal.

Most of the chapters will be found to be quite exhaustive for a text-book, and whilst the tendency of the author is toward conservatism, his conservatism is well tempered with judicious boldness. The only criticism which can be made unfavorable to the work, is that it is not quite up to date, and this may have been unavoidable. The experimental work of Senn in regard to intestinal obstruction, etc.; his bone-plate suture for the rapid restoration of the continuity of the intestinal canal; his rectal insufflation of hydrogen gas for the detection of perforations in the bowels, mark an era in intestinal surgery, but no notice of them is found in this book. Other defects might be mentioned, but they are far overbalanced by the good points of the work. The chapter on "Aneurism and Diseases of the Arteries" is especially satisfactory, occupying fifty pages of the text. In our opinion the fifth edition of Holmes's Surgery is a good book, and deserves a large circulation.

LECTURES ON BRIGHT'S DISEASE. By ROBERT SAUNDBY, M.D. Edinburgh, F.R.C.P. Lond., Emeritus Senior President of the Royal Medical Society, etc. 12mo., pp. vii., 290. With fifty illustrations. New York: E. B. Treat, 1889.

WE wish we could say as much for the other features of the make-up of this American reprint of Dr. Saundby's excellent lectures as we can for the type, which is as clear and readable as the author's style. This is worthy of mention, because publishers do not always show proper consideration for the student's overworked eyes, and appreciation may be an encouragement to persist, to those who do.

Much of the material of these lectures has been previously published, but the preface states that "every chapter has been rewritten, every point has been thought out again." The work is divided into three sections, entitled respectively "General Pathology," "Clinical Examination of the Urine," and "Bright's Disease," these being appropriately subdivided. The present state of knowledge upon all topics treated is concisely set forth, a fair summary of the most prominent views upon debated questions being followed by a lucid exposition of the author's own opinion, and the evidence upon which it is based.

Believing that albuminuria may be without pathological significance, he thinks that *per se* it should not be a bar to life insurance. He proposes an etiological classification of Bright's disease into (1) febrile nephritis, (2) toxæmic nephritis (3) obstructive nephritis. The terms are self-explanatory. All the usual pathological divisions may be found under each of these classes. The first division, however, includes most cases of acute parenchymatous nephritis and of chronic fatty kidney, while the second is specially associated with the small red granular kidney, including chronic lithæmic cases, acute nephritis of gout, acute or chronic cases due to poisoning by vegetable, animal (extraneous or autogenous), or mineral poisons, and certain cases of primary acute nephritis attributed to chill, but in which there is probably an existing dyscrasia. Lardaceous degeneration is not made a special class, because it can be called "Bright's disease" only when associated with chronic nephritis—*i. e.*, the chronic nephritis of chronic pyrexial disease. Albuminuria and Bright's disease are not synonymous; so that even the occurrence of this symptom in general lardaceous degeneration, including the kidneys, does not bring the renal affection under the latter heading. "The Complications of Chronic Bright's Disease" is made a separate chapter. The questions of diagnosis, prognosis, and treatment are treated under each of the different divisions. We cite with approval

the author's opinion that an exclusive milk diet in chronic gouty nephritis is not only unnecessary, but positively harmful. We have frequently met with cases in which the ill results of an attempt to maintain this diet have prejudiced the patient against necessary dietetic restrictions. Dr. Saundby's discussion of therapeutic points is too condensed to be satisfactory, but the advice given is, in the main, judicious, and is evidently based upon an extended experience.

THE URINE, THE COMMON POISONS, AND THE MILK. MEMORANDA, CHEMICAL AND MICROSCOPICAL, FOR LABORATORY USE. By J. W. HOLLAND, M.D., Professor of Medical Chemistry and Toxicology, Jefferson Medical College of Philadelphia. Illustrated. Third edition, revised and much enlarged. 12mo., pp. 84. Philadelphia: P. Blakiston, Son & Co., 1889.

THAT this little book admirably fulfils its purpose as a syllabus for the laboratory, is evidenced by the succession of new editions called for. A highly useful feature in its make-up is the interleaving with blank pages for memoranda, calculations, or more extended notes by the student.

DIPHTHERIA: ITS NATURE AND TREATMENT. By C. E. BILLINGTON, M.D. AND INTUBATION IN CROUP AND OTHER ACUTE AND CHRONIC FORMS OF STENOSIS OF THE LARYNX. By JOSEPH O'DWYER, M.D. 8vo., pp. 326. New York: Wm. Wood & Co., 1889.

To reverse the order of the publishers and take "the best, first," the chapter upon intubation contributed by the author of the operation—for such he is entitled to be called, despite Bouchut's unsuccessful attempts of earlier date—is well worthy of careful study. It is terse in statement, clear in style, and eminently practical in tendency. The operation, its indications, its technique, its complications and its accidents, are fully explained; and the after-treatment is equally well handled.

Dr. Billington's treatise upon diphtheria is not sufficiently full or critical for those who are not acquainted with the literature of the subject; and for those who are, a large portion of it is unnecessary. It has, nevertheless, a positive value as the record of the experience of a careful observer who has enjoyed unusual opportunities to become familiar with the clinical aspects of his subject. The chapters upon symptomatology, diagnosis, prognosis, and treatment are therefore those which give the work its *raison d'être*.

Etiology is perhaps the topic upon which the author lays greatest stress, and he is a staunch upholder of the doctrine of the primarily local origin of the affection. A microbe, not yet positively identified, becoming implanted upon mucous membrane of which the epithelium is inflamed or abraded, gives rise to a chemical poison, which by direct action upon tissues and vessels causes the local diphtheritic process; while absorption of this ptomaine and perhaps of other septic products, gives rise secondarily to the constitutional manifestations.

Treatment must first endeavor to check or combat the local disease; second, to prevent systemic infection; third, to avert the evil consequences of such infection. Local disinfection by means of a spray of carbolic acid and lime water, topical applications of mercuric chloride, and nasal irrigations of warm salt water; together with the internal use of potassium chlorate, tincture of ferric chloride, and mercuric chloride; all in accordance with certain formulæ and methods to which great importance is attached; are, in addition to the obvious points of hygiene and nutrition, the measures chiefly relied upon. Alcohol is freely used in conditions of adynamia, but its indiscriminate use is deprecated.

There is an extended discussion of the value of agents other than those mentioned, which have been vaunted by various observers; and the subject of tracheotomy in laryngeal diphtheria is treated with reasonable fulness; though the important questions of after-treatment are somewhat neglected.

SOCIETY PROCEEDINGS.

GYNECOLOGICAL SOCIETY OF CHICAGO.

Stated Meeting, March 15, 1889.

THE PRESIDENT, CHARLES T. PARKES, M.D., IN THE CHAIR.

(Concluded from page 303)

DR. WILLIAM E. CLARKE spoke of

BLEEDING IN PUERPERAL ECLAMPSIA.

From the earliest dawn of medical science to within recent memory, bloodletting was almost universally regarded and employed as one of the most valuable of remedies. In discussing the curative treatment of puerperal eclampsia, especially in reference to venesection, it may be well to inquire how much the present popular disfavor of the remedy and its disuse by the profession are due to popular clamor, to the caprices of fashion, to the vagaries of pseudo-practitioners, or how much to the advancement of pathological knowledge and the deductions of sound scientific research.

Popular clamor and the blind zeal of the pseudo-scientist and misguided reformer have had very much influence in the matter. But blind and unreasonable prejudice against bleeding has not been confined to non-professional or to illegitimate practitioners.

Allison, in 1856, assumed that the type of diseases had changed from a higher to a lower type, and that while bleeding and other antiphlogistic remedies twenty years before were useful, at that period they were harmful. Dr. Bennett contended that there had been no such changes in the type of diseases; that bleeding and other antiphlogistic remedies were contraindicated, in all internal inflammations, by principles of sound pathology. To the writings of these men, together with Dr. Flint of our own country, are probably due, more than to any other respectable medical writers, the changed views among the regular profession. Still, Dr. Bennett, in the discussion with Dr. Watson on this question, agrees with the latter that we should so bleed as to secure its advantages and avoid its disadvantages.

The speaker, during a stay in Washington, made a very thorough examination of the literature of this subject in the library of the Surgeon-General's Office. He found that the consensus of a very large majority of the eminent members of the profession who wrote on the subject, during this war on bloodletting, is in favor of it, particularly in selected cases of puerperal eclampsia.

He further believes, from his clinical observation in a practice of more than forty years, that in cases of puerperal eclampsia where there is turgescence of the vascular system, or in cases of uræmia, bleeding is called for to relieve vascular tension and to remove damaged blood from the system.

In 1855 he reported to the Chicago Medical Society a case of eclampsia that was promptly relieved by bleeding, after chloroform had been used, only apparently to increase the plethoric condition of the patient. The writers of that day usually described puerperal eclampsia under three distinct varieties: hysteric, epileptic, and apoplectic. The position taken in the report was that chloroform was the only proper remedy in the first variety, and bleeding in the two others.

To the principles recorded in that paper he still adheres, and in some ten cases he had used the lancet with the happiest results. In one case no blood was taken, as it was regarded as hysterical, but the convalescence was far more tedious than in any of the others. In no case coming under his observation has he seen any of the evils attributed to the abstraction of blood, but he believes that he has seen suffering and death which might have been averted by the timely and judicious use of this much-abused but potent remedy, if the attending physician had not been prejudiced, or had had the moral courage to resort to its use. The attention the subject is receiving from the profession is a hopeful indication that venesection is soon to resume its place as a valuable therapeutic measure.

DR. EDWARD WARREN SAWYER, in opening the discussion, said that concerning the subject of eclampsia he had but two points to speak of, and both concern its etiology. He recalled very distinctly a most interesting conversation upon this subject that he had with the late Joseph Freer, who had experimented extensively with reference to ascertaining the condition of the urine in eclampsia, and the effect of that urine upon the lower animals when injected into the veins. His conclusions, or chief conclusion, was that eclampsia was not due to uræmia, as much as popularly thought, but that it was really due to anæmia of the brain; this condition being effected by the œdema of the brain of the eclamptic subject.

The second point which the speaker's practice had demonstrated to him effectually is that the danger or the fatal results of eclampsia are not proportionate at all to the amount of anasarca presented by the patient. In fact, of the four cases of eclampsia of which he had a very distinct recollection, the two fatal cases scarcely presented any anasarca, while the cases that recovered presented an anasarca to a degree that was never before seen by him. In both of these cases the degree of anasarca was such in the genitals that the patient could not possibly approach her knees; yet both cases recovered. In one, vision was nearly lost for a number of weeks; in the other, hearing was greatly impaired. In the fatal cases there was less anasarca than is usual in the primipara, and it was limited to the feet. In one of the fatal cases the urine had been examined during pregnancy, and no albumin found; but within five minutes of the birth of the child she had eclampsia, followed by death.

DR. W. H. BYFORD said that these papers had thrown him into a kind of reverie, causing him to look back to old times and to follow the subject down from the years of which Dr. Clark spoke to the present, recalling what the pathology of the disease was then and what the therapeutics were as compared with the present. At that time, doctors used to consider the pathology of eclampsia as apoplectic in character. They thought there was either a very great congestion of the brain unattended by effusion, or that there was great congestion of the brain attended by effusion of blood or serum, and in the dissections of cases at that time it was a very frequent thing to find clots of blood in the substance of the brain. There were also symptoms indicating œdema of the lungs. Those lesions seem to have been the anatomical pathology of the disease at that time. We had no idea, as at present, of the *etiological pathology* of eclampsia. We supposed that the pressure of the uterus upon the abdominal vessels and those of the chest through the diaphragm, caused hyperæmia of the brain, because of the partial exclusion of the blood from those vessels, both venous and arterial. Pressure upon the abdominal aorta prevented the arterial blood from being thrown so plentifully into the inferior extremities, and diverted it to the brain. We believed that this resulted from the pregnancy, and that the full effect of the cerebral hyperæmia thus caused depended upon some constitutional condition with which we were not acquainted. That kind of reasoning upon the pathology of eclampsia led us to a practice which is very different from the practice of the present time. Tracing the disease to a congestion of the brain, or to an effusion of blood in the brain, we believed the best preventive measure—the best curative measure—was evacuants—something to lessen the quantity of blood in the system and at the same time prevent the large quantity of blood being thrown into the brain through the circulation, giving Nature time to correct herself by delivery, etc.

To sum up his experience in that kind of treatment, he said that he had pursued it until he came to Chicago, twenty years from the commencement of his professional career, and he did not remember that he had seen a patient die of eclampsia until he came here. The first case he saw was in consultation. The patient had eclampsia and was only about six months pregnant. They discussed the subject of treatment, and he was astonished, as she was a strong woman, that nothing was said about bleeding; but venesection had been dead several years in this part of the country, and he could not induce the other consultants to think that it was a proper remedy. That was the first patient he ever saw treated without venesection, and the first patient he saw die. He agreed perfectly with the sentiments expressed in the paper on the etiology of the disease. He thought it perfectly rational to trace it to a kidney origin, as our pathological observations have proven that there is poison of some kind produced by retention of some of the constituents of the urine. Something occurs in the kidneys that prevents their depurating influence, and there accumulates in the blood a considerable quantity of excrementitious matter that ought to be eliminated, which seriously affects the nervous centres. He did not at all subscribe to the idea that cerebral anæmia is necessary to these convulsions in the beginning; he was sure it is not present as the case advances. These cases begin with epileptic symptoms, and they generally end with apoplectic symptoms. He believed in the beginning that there is not much vascular excitement in the brain, but

that the terrible convulsions and the great cramps, especially in the chest, produce such a determination of blood to the brain as to produce organic effects in it.

As to his present ideas with reference to the treatment of eclampsia, he agreed with Dr. Earle in the majority of his conclusions. But in the general way of treating these patients, leaving out the considerations of delivery, he believed it was better for us to begin, especially in patients of strong, plethoric habit, by copious venesection. In the old days when venesection was done, we did not count the ounces of blood as a reason for bleeding no more, but we bled to produce an effect, and sometimes we bled three or four pints at a time. And he thought now if we could have a patient early, and the pregnancy has not terminated, the best thing to do is to bleed to reduce the quantity of blood, and consequently reduce the force of the circulation and acrid character of the blood by the rapid absorption of lymph which follows. After this is done we should give an active cathartic to work off any accumulation in the intestinal canal and produce revulsion. During the whole time after bleeding we should keep the patient constantly under the influence of chloral. Chloroform bears no comparison, in its effects upon eclampsia, with chloral, and one reason is that we do not know how much chloroform the patient is inhaling. Certainly there is no sense in holding a sponge of chloroform to a woman when she is in convulsions, for respiration is suspended until the convulsion ceases; it is impossible to get it into her system while the air is thrown out of the lungs and the chest closed by clonic spasms, but we can give chloral by the stomach or by the rectum, and keep up its influence to a recognizable degree. These remedies must be supplemented by the treatment which Dr. Earle so intelligently presented. He thought very favorably of pilocarpine; it is a most excellent addition because it serves to promote the secretions to such a great degree.

DR. J. S. KNOX said that his introduction in medicine was under the direction of an old and skilful country doctor, who was decidedly in favor of venesection. He used to bleed in labor for irritable os, for rigid perineum, for the prodromal symptoms of eclampsia, and he always bled for eclampsia. He never knew him to lose a case, and he told him he never had lost one when he bled early enough. He was impressed, therefore, with the idea that venesection was the treatment for eclampsia. He had always followed it, and in ten cases that had come under his observation, seven were bled and recovered, three were not bled and died. His treatment has been to bleed, as Dr. Byford expressed it, copiously, drawing from fifteen to twenty ounces of blood from a large orifice, and he never yet had seen a woman so anæmic that he hesitated to employ this method. After the bleeding, he gives half a grain of morphine hypodermatically, and medicines to keep the bowels and kidneys acting freely.

DR. F. HENROTIN said that in his own mind he divided these cases into two varieties. On the one side are the cases that give rise to symptoms long before delivery; cases that are accompanied by a great deal of œdema, both of the genitals and of the limbs; cases that draw attention to the fact that albuminuria is probably present, which is usually found to be the case. And it always seemed to him that those cases having such symptoms were best treated by venesection, catharsis, and pilocarpine. On the other hand, there are a few extremely severe cases occurring in patients who had shown no œdema, who usually had shown no symptoms whatever before delivery, but were supposed to be perfectly healthy, and in whom the convulsions occurred either at the time of labor or several hours afterward. In two of these cases he had seen venesection tried without any effect whatever, while, in the cases that gave rise to œdema, venesection, which has always been followed almost as a routine practice by him, has always seemed to be of a great deal of benefit. Those patients that were affected very late in pregnancy or after delivery, that did not give any symptoms whatever, where albuminuria was not present at all, seem not to have been affected in any way whatever by venesection, but seem to have been helped by morphine and narcotics; while those that resembled more particularly cases of the uræmia that we get after scarlatina, those cases of supposed large, white kidney in which albuminuria is a prominent symptom, those cases seem to be affected favorably by venesection, and in such cases coming under his observation, with one exception, all recovered. In regard to drugs in this disease, he believed from personal experience that the giving of pilocarpine hypodermatically, while the patient is unconscious, is capable of actually drowning the patient by the excessive flow of saliva and increased pulmonary secretion, so that he would advise caution in its administration when the patient is unconscious.

DR. W. W. JAGGARD said that it is possible that in certain cases the nephritis of pregnancy may be an example of infection. But the sporadic occurrence of the disease, the apparent selection of primiparæ, and cases of multiple pregnancy, tend to show that the operation of this factor is not general.. Staude calls attention to the predisposition to the disease observed in case of pelvic contraction and where the fœtal head is of uncommon size. Pressure on the pelvic bloodvessels causes an increase in the general blood-pressure that ultimately reacts upon the kidneys. Eclampsia appears among the rich and poor alike. Its victims are oftenest young, healthy, blooming women in whom it is reasonable to suppose the physiological resistance of the tissues is not notably lessened.

Dr. Nelson and Dr. Merriman have touched upon an important item in prognosis. What is the probability as to recurrence of eclampsia in subsequent pregnancies? A guarded answer must be returned. In general, eclampsia in a first pregnancy seldom means a recurrence of the disease in succeeding gestations. When all symptoms of nephritis disappear within a short period after delivery, the probability of immunity becomes almost a certainty, so that eclampsia in a first pregnancy, *per se*, is not an indication for the prevention of conception nor for the induction of abortion. If, however, symptoms of Bright's disease, no matter however latent, persist, the patient should be warned against conception. In case of conception and the development of albuminuria early in pregnancy, he was of the opinion that the induction of abortion ought to be seriously considered.

The value of the hot-water bath is greatest in the prevention and least in the cure of eclampsia. Used as described by Dr. Earle—the Vienna plan—it is by far the most efficacious procedure that we possess in the prophylaxis of the disease.

As to the treatment of eclampsia during pregnancy, the weight of evidence and opinion is decidedly in favor of an expectant plan of treatment, unless abortion or premature labor is imminent. Wait until the seizures are well over and until convalescence is established before interrupting pregnancy. If, however, abortion or premature labor is imminent, the indication is to aid in the evacuation of the uterus.

In eclampsia during labor, three indications are clear:

1st. After the insertion of a gag and the protection of the woman's body by pillows and the like, the indication is to control the convulsions by profound narcosis. The choice of remedies is not so important as that the narcosis shall be deep and continued. Chloroform is by far the best agent to control the seizures, while the narcosis can best be maintained by large doses of chloral and the bromides exhibited *per rectum*. Winckel,[1] who relies exclusively upon chloroform inhalations and chloral *per rectum*, has had only seven deaths in ninety-two cases. As at present informed, this result is better than that obtained by any other plan of treatment on record.

2d. The second indication is to evacuate the uterus as rapidly as may be consistent with the safety of the mother and child. Experience teaches that the convulsions cease when labor terminates in about one-third of the cases, in one-third they grow less frequent and severe; only in the remaining one-third do they continue without change. Early in the first stage of labor, before effacement of the cervix and dilatation of the os, puncture of the membranes is commonly the best means to accelerate labor. The escape of the liquor amnii is not infrequently followed by an abatement of the convulsions. Later in the first stage, after effacement of the cervix, digital dilatation of the os externum is often indicated. It is seldom necessary to incise the os externum. Delivery may be completed by the forceps or version and extraction, according to the conditions of the concrete case.

3d. The third indication is to eliminate the retained excrementitious products of the urine by diaphoresis, purgation, and diuresis. The hot pack is probably the best means. He thought Dr. Earle would encounter some difficulty when he attempted to put an eclamptic in the hot-water bath, besides running the risk of drowning his patient. The vapor bath, by means of the alcohol lamp, is efficient and easily exhibited. Pilocarpine must be used with extraordinary caution, only in the beginning of the disease, when the coma is light, the pulse full, and the respiration free. Deep coma, weak heart, and beginning œdema of the lungs are absolute contra-indications. The evidence upon this point, brought forward by Fordyce Barker, Kleinwächter, Sänger, Welponer, Schramm, Klotz, Carl Braun, Winckel, Schröder, and others is decisive. The unqualified praise this remedy has received this evening must be taken *cum grano salis*. Dr. Henrotin is right in saying there is grave danger of drowning the woman in her own secretions.

Finally, there comes the question of bleeding. Every speaker has commended bleeding in the strongest possible terms. There may have been slight differences of opinion upon other points, but all unite upon the item of venesection. Bleeding is the specific treatment of eclampsia. But no one has given a reason why he bleeds, neither has anyone presented a series of cases that demonstrate the value of phlebotomy. There are at least three good reasons why we should not bleed in uræmic eclampsia.

1. The procedure is without important effect upon the demonstrated cause of the disease. The amount of excrementitious material that can be eliminated by bleeding is comparatively trivial. Blood pressure cannot be depressed for any considerable period of time, unless the patient be dangerously exsanguinated. Hemorrhage into the brain, as a consequence of puerperal convulsions, is an extremely rare finding. The indication for bleeding in eclampsia is not stronger than in the convulsions of Bright's disease in the male and non-pregnant female. None of the Fellows present, he was certain, would bleed in the latter affection.

2. Clinical experience teaches that much better results are now obtained without bleeding than were formerly observed when venesection was commonly practised. In support of this proposition, the verdict of the Vienna (Kucher) school of obstetrics must be cited: "In the Vienna clinics, where the results of treatment are far better than anywhere else," bloodletting has been completely discarded. Winckel's (Munich) statistics have already been mentioned—ninety-two cases, seven deaths. In Schroeder's clinic (Berlin) bleeding is no longer practised, on the ground that better results are obtained since its rejection.

3. The weight of opinion is opposed to venesection. In this connection names are to be valued like coins. C. Braun, Gustav Braun, Josef Spaeth, F. Winckel, Schroeder, have expressed themselves in no equivocal terms as opposed to bloodletting.

If bloodletting in eclampsia is unphilosophical, if it is opposed by clinical experience and the weight of professional opinion, upon what grounds can this practice be tolerated? If we must bleed, let us "bleed the woman into her own veins" by the use of veratrum viride.

The experience of one individual in private practice or in our small lying-in hospitals does not count for much. It can have but slight weight in influencing the conduct of others. Yet, as the personal experience of each member had been the basis of his remarks this evening, the speaker felt like adding his own testimony. Up to the present, in about thirty cases of eclampsia, he had not observed a clear indication for venesection. His observation of the cases of others in which bleeding was allowed has failed to convince him of the value of the procedure. Some of these cases were a little remarkable and cannot be fairly cited in this connection, since at the same time with free bleeding the patient's blood was saturated with chloroform, morphine, chloral, and the bromides. It was a question as to the cause of death, whether it was the Bright's disease, the bleeding, or the artificial toxæmia.

In the treatment of eclampsia one item has been neglected. It is necessary to use all precautions against septic infection that so frequently occurs.

[1] Lehrbuch der Geburtshülfe, 1889, p. 590.

New Hospital in Wilmington.—The corner-stone of the Delaware Hospital, in Wilmington, was laid August 18th of this year. The grounds and buildings, when completed, will cost $20,000. Of this sum $16,000 is already in hand.

CORRESPONDENCE.

PHENACETINE POISONING.

To the Editor of THE MEDICAL NEWS,

SIR: The increasing favor of this new member of the carbolic acid group among general practitioners has induced me to report the following case from poisoning by its use:

Mrs. W., aged thirty, married, no children, slight, anæmic, of a nervous temperament, has been a great sufferer for years from a chronic pelvic trouble, an endometritis, and associated with it neuralgia of a most persistent character in the form of migraine or tic, in frequent paroxysms, occurring two or three times a week. Recently she has been on arsenic and iron and has greatly improved in general health. For her neuralgia she has taken antipyrin and antifebrin, and many other of the approved anti-neuralgic remedies.

Antipyrin and antifebrin she has taken frequently on different occasions in fifteen-grain doses four or five times daily, without any of the characteristic symptoms. She has not, however, received much benefit from their use. Last week I was hastily summoned to prescribe for her in one of her usually severe attacks. In recalling the previous inefficiency of antipyrin, I decided to give her phenacetine. Twelve powders each containing seven and a half grains were given, a powder to be taken every two or three hours. Six hours after leaving my patient I was again urgently requested to see her, and found her in a state of collapse, severe præcordial pains, and great dyspnœa, lividity of the whole surface, nails, lips, and conjunctiva; great restlessness, inability to lie down or stand; was supported in a semi-recumbent position. Temperature at the time of my first visit was 101½° F. Involuntary movement of the bowels occurred once; pulse below normal, slow and soft; cold perspiration; pupils slightly dilated. She remained in this condition for about ten hours, slowly improving under the use of ammonia and alcoholic stimulation. The blueness did not fade for more than three days. Convalescence was very slow, the patient not being able to be around her room for over a week. Three powders of seven and a half grains each were taken during the six hours.

While I regard phenacetine as the most reliable remedy we have for any nerve pain, never requiring it in larger doses than two or three grains, frequently repeated, if necessary, the apparent tolerance of the patient for the drugs antipyrin and antifebrin, was strikingly offset by the use of phenacetine.

W. C. HOLLOPETER, M.D.

1408 N. 13TH ST., PHILADELPHIA.

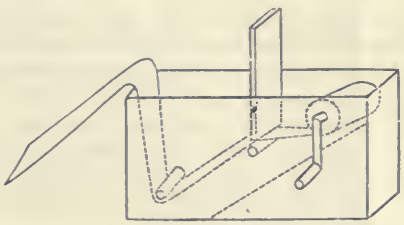
NEW INVENTIONS.

A MACHINE FOR PREPARING PLASTER BANDAGES.

BY G. G. DAVIS, M.D.,

ASSISTANT SURGEON TO THE EPISCOPAL AND ORTHOPÆDIC HOSPITALS, PHILADELPHIA.

HAVING occasion to use plaster bandages frequently, and the machines at hand not working satisfactorily, the following was devised: A box was made, fourteen inches long, five inches wide, and about seven inches high. A winch, made of thick wire and filed flat on its sides and tapering, was placed at one end of the box, and a round peg three-fourths of an inch in diameter placed from side to side in the opposite corner. One edge of the end of the box was rounded off to allow the bandage to glide over it. The bandage is passed over the rounded edge down under the peg, and wound on the winch. A sloping false bottom placed inside causes the plaster to gravitate to one corner. Between the winch and the peg in the corner, a little above a straight line joining the two, is placed another peg. The bandage passes over this peg on its way to the winch. Slots are cut in the sides of the box and a board a quarter of an inch thick placed in it, its lower edge being slightly rounded and resting on the upper surface of the bandage as it passes over the peg. It is kept firmly pressed down on the bandage by a couple of rubber bands (not shown in the illustration) passing from the top of the board to tacks driven in the sides of the box.



The bandage being passed over the edge of the box, it is carried beneath the peg in the corner, between the peg in the middle and the upright board, and fastened around the winch. Fill the box with plaster up to the middle peg. On turning the crank the bandage is carried through the plaster, over the middle peg, the upright board grinding the plaster in and scraping off the surplus, and then wound around the winch. If desired, a wedge-shaped strip of tin with a slot cut in the broad end may be used to carry the bandage beneath the first peg. The bandage being threaded in the slot the tin is passed under the peg, and drawn out, the bandage following.

It is almost useless to attempt to prepare bandages by any machine that does not rub the plaster in the meshes of the stuff, or that winds them while they are nearly or quite vertical; in either case the result is that the plaster drops out and the bandage is useless. The only objection that has yet been made to this machine is that it rolls the bandages so tight that they require rerolling before use. Practically, this does not amount to much, and the machine will be found to work fairly satisfactorily.

NEWS ITEMS.

An Official Investigation of Artificial Foods.—At the recent meeting of the Association for the Advancement of Science, Dr. F. Hoffman, of New York, read a paper on infant foods, in the course of which he stated that the chemists of the United States Agricultural Department were about to begin the work of investigating the different artificial foods and infant foods now on the market.—*The Medical Record*, September 14, 1889.

Leprosy in Hawaii.—It is estimated that there is one leper to every forty of the inhabitants of the Sandwich

Islands. Speaking of leprosy, we notice that a Chinese leper was recently discovered in the Sacramento jail. He had been sent there for refusing to pay a poll-tax.

Poisoning with Corned Beef.—Thirty-one persons at Findlay, Ohio, were poisoned by eating corned beef, and it is feared that some of the cases may terminate fatally.

The Congress on Hypnotism.—The following resolutions were adopted by the International Congress on Hypnotism held in Paris last month:

1. Public exhibitions of hypnotism or magnetism should be forbidden by government.

2. The use of hypnotism as a therapeutic agent should be restricted to practising physicians.

3. It is to be hoped that the method and practice of hypnotism will be included in the medical education of students.

Jelly-fish Sting.—Bathers who have encountered the long tentacles of a medusa will be pleased to know that the "sting," or erythema, may be speedily relieved by the application of water rendered alkaline by common washing soda, in the proportion of an ounce of soda to about two quarts of water. Dr. B. M. Richardson states in the *Asclepiad* for September, that he has personally tested the efficacy of the treatment, and has also used it successfully in several severe cases.

The Dangers of Carbolic Acid.—The following letter of Dr. Th. Billroth, of Vienna, has been published: "I have lately seen four cases, in which fingers which had suffered a most insignificant injury became gangrenous through the uncalled for application of carbolic acid. Carbolic acid is now much less used in surgery than formerly; we have only gradually become acquainted with its dangers. The acid may not only cause inflammation and gangrene, but also blood poisoning, and so may even prove fatal. It is useful only in the hands of a skilful surgeon, and ought never to be used without his advice. The best lotion for recent injuries is the ordinary lead lotion, which can be bought at any chemist's. The best antidote in carbolic acid poisoning is soap, which should be taken immediately and repeatedly until all symptoms of poisoning have disappeared." —*Lancet*, August 31, 1889.

Female Medical Students in India.—Female medical students in India need not complain of lack of encouragement. The Viceroy of India, during his term of office, has placed at the disposal of the Central Committee of the Lady Dufferin Fund five silver and two bronze medals for annual competition among the female medical students.

Medical Minims and Surgical Saws.—We quote the following useful axioms from the *Boston Medical and Surgical Journal* of September 5th:

The most effective instrument in medical surgery is the nail-brush.

The patient's interest in his own case is clinical; it is rarely pathogenetic, and never necroscopic.

A long prescription maketh no one fat but the druggist.

Better is aqua fortis with a ready stomach, than the best drug of the pharmacopœia and retching therewith.

Woman has some organs outside the pelvis.

Berlin makes a physician learned; Vienna skilful; the bedside wise.

The same channel brings their bread alike to the harlot and to the virtuous midwife.

The truly *necessary* calls upon a physician will about suffice to pay his tythes.

In the domestic republic the family physician is nominated by the husband, but confirmed in executive session by the wife.

The good medical Samaritan must needs look to it lest he be sued for the quality of his wine and oil, the speed of his beast, and the roominess of the quarters he provides in the inn. Albeit he gives of them all the best he has, he may find that the one who has most fallen among thieves is himself.

London Post-graduate Courses.—It has always been a reproach to London that the unrivalled clinical material of its numerous hospitals is not fully utilized for the purposes of medical education. It is not that teaching power is wanting, says the *British Medical Journal* of September 7th; on the contrary, the metropolitan schools could furnish among them a body of men thoroughly fitted to make London the centre of the medical world, as it undoubtedly ought to be. Owing to want of organization, however, a large amount both of material and teaching power is wasted. Nowhere is the loss of potential educative energy more evident than in the hospitals to which no medical school is attached. It is, therefore, with peculiar satisfaction that we hail the announcement that the medical staffs of several hospitals have decided to unite their forces and give courses of instruction to qualified medical men in the various important branches of medical science and practice which these institutions represent. The teaching is intended to be thoroughly practical, and the convenience of men engaged in the active exercise of their profession has been studied in the arrangement of the hours at which the courses will be held.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM SEPTEMBER 10 TO SEPTEMBER 16, 1889.

By direction of the Acting Secretary of War, the leave of absence, on surgeon's certificate of disability, granted FREEMAN V. WALKER, *First Lieuteuant and Assistant Surgeon*, in S. O. 92, April 20, 1889, from this office, is extended one month on surgeon's certificate of disability.—*S. O. 211, A. G. O.*, September 11, 1889.

By direction of the Acting Secretary of War, FREEMAN V. WALKER, *First Lieutenant and Assistant Surgeon*, is relieved from duty in the Department of Texas, and will, upon the expiration of his present leave of absence, report in person to the commanding officer Jackson Barracks, Louisiana, for duty at that station, and by letter to the commanding general Division of the Atlantic.—Par. 2, *S. O. 212, A. G. O.*, September 12, 1889.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

HOT-AIR INHALATIONS IN PULMONARY TUBERCULOSIS.[1]

BY E. L. TRUDEAU, M.D.,
OF SARANAC LAKE, N. Y.

THE exact value of any therapeutic measure in the treatment of phthisis can only be determined after a considerable lapse of time and a comparison of the clinical reports of different observers made on an extensive scale. The present notes, therefore, which only embrace the study of four cases treated for periods varying from one to a little over four months, can necessarily constitute but a very meagre contribution to the clinical side of the question. Inasmuch, however, as the inhalation of hot air has been put forward as a distinctly antiparasitical method, the report of some observed facts bearing on the bacterial study of these cases may, even at this early date, prove of some value in reaching a conclusion regarding its merits as a specific.

The literature of the subject has until recently been confined to the observations of Louis Halter,[2] published in September, 1888, on the immunity of lime-burners from pulmonary phthisis; to the work of Dr. Krull[3] on hot-air inhalations for tuberculosis, and to a paper published by Dr. Louis Weigert in the *Medical Record* for December, 1888. More recently articles by A. Jacobi,[4] Renzi,[5] Kohschutter,[6] and Sears,[7] reporting the results of their observations in treating phthisis by this method have appeared. Dr. Weigert's claims were to have discovered in hot-air inhalations a specific treatment for tuberculosis, and that this disease could be cured by the use of an apparatus devised by himself for the purpose.

In his article, hot-air inhalations are distinctly put forward as a specific for pulmonary tuberculosis. They are not held to be merely a therapeutic measure of more or less service, and no influence other than their efficacy in checking the growth and multiplication of the tubercle bacillus is claimed for them. Based on well-observed facts relating to the narrow temperature range of this microbe, the diminution of virulence which may be brought about in certain pathogenic bacteria by growing them at high temperatures, and the efficacy of discontinuous sterilization, this plan of treatment is worthy of serious consideration.

Are inhalations of dry hot air capable of preventing the growth of the bacillus tuberculosis in the lungs of living individuals, or of diminishing the virulence of this microbe? The present notes are but a collection of clinical facts and bacteriological observations made by the writer in attempting a solution of this question. The clinical study includes four cases: the first three will be briefly outlined, while the fourth, for reasons that will appear hereafter, will be given more in detail.

These three patients had all been ill less than a year, and presented the rational and physical signs of moderately advanced pulmonary tuberculosis in its first stages; in one only was a small excavation present. The sputum, which contained bacilli in all the cases, was examined every month, and careful records of the vital signs were kept. These patients took the treatment continuously for periods of one month, six weeks, and a little over three months respectively; the time of inhalation was rapidly run up to four hours daily, divided into two sittings, during which the temperature of the inhaled air (as measured by the thermometer on the mouthpiece), was maintained over 200° C. (392° F.).

The results were as follows: In the first and second cases slight improvement in all the symptoms occurred at once, but the patients became discouraged and could not be persuaded to continue the inhalations. The third patient kept up the treatment most rigorously for over three months without the least noticeable effect.

The history of the fourth patient before and after treatment was as follows:

January 28, 1889. R., clerk, aged twenty-three; no family history of phthisis. Taken ill July, 1888, with hæmoptysis; has all the rational signs of progressive pulmonary tuberculosis in its first stages; has lost ten pounds. Both lungs are involved. At right apex prolonged bronchial expiration, with fine and coarse râles both back and front, involving the upper lobe. At left apex breathing good, except under the clavicle, where some fine crackles and loss of breath-sounds prevail. Temperature P.M. daily,

101½° to 102°; respiration 24; pulse 100 to 120. Expectoration moderate in quantity and purulent.

Began treatment February 18, 1889, and inhaled air at 200° C. to 210° C. (392° to 410° F.) four hours daily, with but trifling intermissions, until June 20, 1889. A complete record of the vital signs was kept, and the sputum was examined every five weeks for bacilli. His condition at the end of treatment (a little over four months) was as follows: *Physical signs*, show marked decrease in the amount of râles, which have entirely disappeared over right scapular region. *Rational signs:* Weight has increased 10 pounds; pulse shows an average decrease of 8 beats; respiration has fallen from 24 to 19 on an average; temperature usually about 2° Fahr. lower; sweats have disappeared; dyspnœa improved; no hæmoptysis; expectoration has diminished two-thirds in quantity and is still muco-purulent in the morning. The improvement reached its height about three months from the inception of treatment; some of the ground gained was slowly lost during the fourth month, though the inhalations were faithfully continued.

This brief clinical study does not furnish evidence which differs materially from that usually obtained on the trial of many specific methods of treatment for tuberculosis hitherto put forward and long ago abandoned. The improvement which manifested itself in one case, though marked, was no greater than was observed to occur at the same time, from climatic and hygienic treatment alone, in several of the man's fellow patients. Whether or no the favorable change noted in his condition can be ascribed to any specific effect produced on the germ element of his disease by breathing the hot air will hereafter be shown conclusively by the inoculation tests to which his sputum was subjected.

These brief clinical notes may be said to furnish no positive proof as to the therapeutic value of the method.

The bacteriological study was as follows: The sputum of all four cases was examined before treatment, at intervals of five weeks during treatment, and as soon as it was abandoned. *In every instance the bacilli were found.* No appreciable influence therefore was produced upon this most important element of the disease.
